However, there are a few cautions to be observed and suggestions that may be made. Babies cannot stand rough play with their fathers immediately after eating; it usually causes regurgitation of food, and, furthermore, this is the time for sleep. Infants should be protected from tickling. The morning bath can be a happy time for both mother and baby. Feeding time should be a pleasant experience without tenseness. The urgency that some mothers feel about the necessity of giving their infants a measured amount of food at each feeding time creates unnecessary tension and establishes bad eating habits. Well babies should not be forced to eat. Late afternoon is a suitable time for play; some regularity is desirable, for the baby must learn that he cannot be played with at any or every time he fancies.

Cleanliness.—Once a day a baby should be given a bath in water at normal body temperature (between 35° and 38° C. [95° and 100° F.]). The temperature should always be tested (using the mother's elbow) before placing the baby in the water; this will prevent accidents and enhance the baby's pleasure. There are a variety of acceptable tubs. It is essential, however, that the tub be firmly placed and incapable of being tipped over, and it should be of a kind that can be readily cleaned. In bathing an infant another point to remember is that the skin of a wet baby is slippery and that the mother must always have a firm hold of her baby when he is in the tub. First she lowers the baby's buttocks into the water. One hand firmly grasps the baby's right arm above the elbow near the shoulder; the remainder of her hand supports his back, and her wrist and forearm support his neck and head. The mother's other hand is then free to cleanse the baby's body with a dampened wash cloth and a small amount of a mild soap. A minimum amount of soap should be used. When baths are skilfully given babies soon learn to enjoy them.

Since it is characteristic of infants to put objects in their mouths and since the mouth is one of the most common portals of entry for disease-producing microorganisms it is essential that hands, toys and eating utensils be kept clean.

Keeping a Well Baby Well.—Barring accidents or the occurrence of the few diseases of unknown cause or those for which there is no known treatment, it is entirely possible through the application of known knowledge to maintain a baby in a state of optimum health throughout the first year and beyond.

The rules for keeping a well baby well are simple but important, as follows:

1. Proper feeding (see *Infant Feeding* below).

2. Preventing infectious disease. The rules governing the prevention of exposure of infants to infectious diseases are a direct application of techniques established years ago in contagious-disease hospitals for the prevention of spread of infectious disease from one patient to another. The success of antibiotics has often led to carelessness in these matters; however, to ignore well-established, effective rules of sanitation because cures are available is comparable to being careless with matches because the city has a good fire department.

The baby should have a room or a corner that belongs to him alone. The most convenient place in the daytime is a room adjoining the place where the mother spends most of her time, usually the kitchen. No one is permitted in the baby's room except well people with washed hands and clean clothes. If any member of the family is suffering from a common cold or other infectious illness he must stay out of the baby's room or corner.

In case the mother has a cold and it is necessary for her to take care of the baby during this period, she can prevent the baby from contracting the cold if she will observe the simple aseptic technique that is known to all pediatric nurses, modified for home use. While caring for the baby the mother wears a mask of gauze over her nose and mouth; she washes her hands with soap and water and dries them on a clean towel and, without touching contaminated objects outside the baby's room, she enters the room and slips into a loose, sleeved cotton gown that covers her clothing. With these precautions she is ready to take care of the baby, and it is perfectly possible for her to do so without transmitting her cold. The gown used in the baby's room should never be used for any other purpose than that for which it is intended and should be kept in the baby's room except when it is being washed. After scrubbing her hands and getting into her gown the mother does not touch her face or things that she has handled with unwashed hands.

Young babies do best when kept at home; traveling with small babies invites the possibility of exposure to infections. Visitors are invited to look at but not handle babies. If the visitor has a cold the baby is not brought out for inspection. Persons with infectious disease should not come closer than six feet to a well infant and must cover coughs and sneezes.

3. Immunizations. These are available for diphtheria, tetanus, whooping cough and poliomyelitis. Babies under six months are not susceptible to measles provided the mother had measles before she became pregnant. After babies lose their natural immunity they may be protected by the use of proper immunization technique.

4. Cleanliness (*see* above). It is important to remember that not all bacteria are harmful and that it is not necessary to observe absolute surgical asepsis in order to prevent the occurrence of illness of infectious origin. Absolute cleanliness (asepsis) is necessary, however, when persons in the household are suffering from or have recently suffered from colds or other infectious illness, or when the baby may be exposed to persons whose state of health is unknown to the mother. When all members of the household are well and free from illness simple cleanliness suffices for all health purposes.

5. Preventing accidents (*see* below).

6. Good hygiene. This requires provision of opportunity for restful sleep, frequent changes of linen, daily outdoor airing (weather permitting), sun baths when recommended by the baby's own physician, opportunities for free play consistent with the age of the infant, an abundance of love and affection, together with the application of all the foregoing rules.

7. Pediatric care. The mother and the father can act sensibly and with good judgment only when they are informed concerning the above rules. The pediatrician will assist them with problems they do not understand.

Accident Prevention.—Accidents that can happen to the infants are relatively few, and if the subject is given a little thought most of them can be prevented. A thoughtful mother can invent most of her rules and they can be effective. However, the following are given as examples: (1) when carrying a baby always be sure to have a firm hold—babies wriggle, squirm and jump at unpredictable times; (2) never leave a baby alone on a bath table or examining table or any other surface from which he might fall; (3) when bathing a baby always hold him securely; (4) never hold or carry hot objects above a baby; (5) remove pointed or sharp objects from the baby's reach; (6) be sure the slats on the side of the baby's crib are close enough to prevent the baby from getting his head through; (7) do not give the baby easily breakable toys; (8) very small toys are to be avoided; the baby may choke on them; (9) toys covered with lead paint or water-soluble stains are to be avoided; (10) plastic sheets and bags must be kept completely out of reach of babies and small children, since they may be slipped over the head and may then cling to the face and cause suffocation.

Sun Baths.—When weather and temperature permit, sun baths are usually recommended, since exposure to the sun's rays, and

to sky shine for that matter, transforms substances in the skin to materials that have vitamin D activity. While vitamin D preparations can be given by mouth when sun-bathing is impossible or impractical, it is believed that sensible exposure to the sun is beneficial. While there is no agreement with reference to the precise age at which sun-bathing can best be started, it is probable that most babies can be safely exposed outdoors, temperature permitting, after the age of two or three months. The baby's eyes should be protected from direct exposure to sunrays, and direct exposure to the glare of a cloudless sky on a summer day is also evidently unpleasant for the infant.

The time of exposure naturally varies with the season of the year, the time of day, the age of the infant and character of skin. It is wise to avoid exposure in midday when the sun is hottest. It is often recommended that first exposure be for as short a time as two minutes. Succeeding exposures can be gradually increased until tanning occurs. It must be remembered that babies do not tan so deeply as adults do and that they burn much more easily. The physician should be consulted on how much sun each baby needs.

Clothing.—The chief object of clothing is comfort. Babies should wear only a sufficient number of garments to keep them warm and comfortable. In newborn babies the temperature regulating mechanisms may not be fully developed and therefore they may need extra clothing to maintain body temperature. If there is suspicion in the mother's mind that her infant is wearing too many clothes, it is usually possible to tell by observing the presence or absence of perspiration on the baby's back. The mother may pass her hand over the baby's back under the shirt and if she finds the skin wet with perspiration it is almost certain that the child is overclothed; if on the other hand the skin is warm and dry to touch and the baby is otherwise apparently comfortable and happy, the amount of clothing is probably appropriate. Cotton clothing is generally most comfortable next to the baby's skin and is easier to wash than most other materials. The baby should wear a hat or a bonnet on cool days out-of-doors.

Sleeping Out-of-Doors.—Fresh cold air is stimulating and invigorating even to quite small babies. However, good judgment must be used in placing babies out-of-doors to sleep. Weak or very small babies require control of external temperature and are best kept in the house. A healthy, vigorous baby gradually can be accustomed to cool or cold air provided he is appropriately covered. Some overzealous mothers have permitted frostbite to occur in babies' cheeks and on the backs of their hands. While these usually are not serious, they are to be avoided. After frostbite, hard lumps may appear beneath the skin of the frostbitten area and persist for weeks.

INFANT FEEDING

Breast Feeding.—The ideal food for the young infant is human milk. It supplies all of the nutrients in amounts and variety necessary for good growth and development provided the mother is in good health and is eating a nutritionally satisfactory diet. One possible exception to the nutritional adequacy of human milk is vitamin D, but this can be obtained from exposure to sunlight.

The yellowish fluid that is secreted before breast milk makes its appearance is known as colostrum. The amount varies greatly. Colostrum alone is secreted for a period of from two to four days after delivery; after this comes a transition to breast milk that is complete at the end of about three weeks.

It has long been held that colostrum may confer some degree of immunity on infants but, however that may be, its removal from the mother's breast by the infant is of importance to the establishment of lactation. Early nursing also encourages early contraction of the mother's uterus.

The composition of human milk varies, as does that of other foods, within a rather wide range. According to P. C. Jeans the approximate percentage composition of human milk is as follows: fat 3.5%; sugar 7.5%; protein 1.25%; lactalbumin 0.75%; casein 0.50%; total ash 0.20%; calcium 0.032%; magnesium 0.004%; potassium 0.041%; sodium 0.011%; phosphorus 0.013%; sulfur 0.014%; chloride 0.032%; iron 0.0001%; copper 0.00003%. In addition breast milk contains traces of other minerals plus identified and unidentified vitamins. The amount of breast milk is usually suited to the needs of the infant. Some mothers can nurse two babies when necessary.

Successful nursing implies that the mother must be free from debilitating disease, that she eat adequately (but not excessively so that she gains unneeded weight) and that she be emotionally adjusted. Adequate rest is necessary. Exercise should be moderate. Home surroundings should be as pleasant and as congenial as possible, and in all these things the husband plays no small part. Professional medical attention is also sometimes required and is always helpful.

In addition to the other good reasons for encouraging breast feeding it is emotionally satisfying to both the mother and infant. Nursing time is often the one time when the mother can relax and enjoy her baby. When she nurses her baby there is no formula to worry about and there is no concern when the infant does not take all of an allotted formula.

Cow's Milk.—When the nutritional needs of infants cannot be met with human milk, other means of supplying these needs are available. Infants who do not receive human milk, however, may require certain nutrients in amounts greater than are present in breast milk. Cow's milk approaches a perfect food only for the baby calf. Furthermore, in no species of animal is milk alone the sole source of food for more than a relatively short period after birth. Infants soon require supplementary foods just as young animals do.

The milk formula for the newborn baby is generally made up of milk, added water and a carbohydrate (one of several sugars or mixtures such as lactose, maltose-dextrin mixtures, glucose and sucrose). It is common practice in the calculation of formulas to give from 1 to 1½ oz. of milk per pound of body weight. One and one-half ounces of milk supplies approximately 3.4 g. of protein and 0.12 g. of calcium per kilogram, together with other minerals, lactose, fat (apparently sufficient for the infant's needs), water and vitamins—notably vitamin A, riboflavin and some thiamine and niacin.

At first the total fluid volume of the formula is in the neighbourhood of 2½ to 3 oz. per pound of body weight. Later the volume is diminished. Thus after determining the amount of milk required, the difference between the calculated amount of milk and the calculated volume of the formula is made up by adding boiled water.

Babies need approximately 50 cal. per pound of body weight. This is easily calculated. The amount supplied by the milk in the formula is calculated on the basis of the fact that average cow's milk supplies 20 cal. per ounce. The difference between the total caloric need and the caloric value of milk in the formula represents the number of calories that need to be added to the formula to make it supply the necessary energy value. This is usually done by adding an appropriate amount of carbohydrate in the form of one of the sugars. Most sugars contribute approximately 120 cal. per ounce. More than 1½ or 2 oz. of sugar is seldom required.

The rapidly growing healthy infant soon is able to take whole undiluted pasteurized milk or unsweetened evaporated milk diluted to the equivalent of whole milk by the addition of an equal amount of water. Full-strength powdered whole milk also may be used.

In bottle feeding infants it is essential to observe strict cleanliness in the preparation of formulas and to refrigerate all bottles whose contents are not consumed at once. There are many ways of preparing formulas, but the object of all of them is to attain a clean (pasteurized or sterilized) product and to keep it safe until the time of use.

Goat's milk approximates cow's milk in nutritive value and generally may be used as a substitute, particularly if the infant is allergic to cow's milk. When using goat's milk it is especially important to be certain of the cleanliness of the supply and that it has been properly pasteurized. Powdered and evaporated goat's milk are also available. Soybean preparations may also be used as substitutes for cow's milk.

Supplemental Foods.—Except in the case of breast feeding, and then only for a short time, the infant can rely on no single

food to supply his total nutrient needs. The early supplementation of the diet with nutrients known to be essential for good growth and development is necessary. Furthermore, it is desirable to start early the cultivation of good food habits with relation to foods other than milk.

The first supplement for babies fed both human and cow's milk is vitamin D. It may be started in the first week with the addition of vitamin D concentrates or the pure vitamin. The infant apparently needs no more than 350 units of vitamin D per day, although the dose usually given is 400 units. Doses above 1,500 units per day tend to inhibit the appetite when given over a period of time, with the result that the growth rate is impaired.

Because the vitamin C content of cow's milk decreases on storage it is necessary to supplement the infant's diet at an early age with foods containing this vitamin. In North America it is a common practice to use orange juice, tomato juice or other fruit juices blended with acerola (West Indian cherry) juice, which is by far the richest of all fruits in vitamin C. In Australia, black currant juice and papaw juice sometimes replace citrus juices. In the United Kingdom rose hips syrup is popular. Orange juice can be started a few days after birth and increased rapidly up to two or three ounces at the age of three months. Advances in the technique of canning and freezing orange juice make it possible for these juices to supply an abundance of vitamin C at all times of the year, even during the season when fresh oranges are not easily obtainable. In addition to supplying natural vitamin C, fruit juices contain other valuable nutrients.

Iron-bearing food supplements are also essential for the infant fed on cow's milk, because a baby fed on this type of milk alone will tend to develop an iron deficiency anemia after a period of several months. For this purpose and to encourage the baby to learn to like a variety of foods it is common practice to start strained vegetables and fruits, meat, egg yolk and cereal at an early age. All these supply needed iron. Good cereal sources of iron are the whole grain cereals, notably oatmeal, and specially fortified cereals.

Home-prepared strained fruits and vegetables for infants have been replaced largely by specially prepared, high-quality, commercially processed foods, available in jars and cans and, after 1960, also as instant dry frozen foods requiring only the addition of water before feeding.

The supplementation of the cow's milk diet with food sources of thiamine and possibly other members of the B-complex group of vitamins is generally regarded as desirable. Strained meat, whole grain cereals (oatmeal or specially fortified cereals) and many fruits and vegetables all provide supplements of thiamine. Egg yolk is a good source, and fruits and vegetables are better sources than highly refined cereals.

At about six months the baby has often developed sufficient skill with his hands to permit him to start feeding himself with a spoon. At this time he sits easily and comfortably and should be encouraged to feed himself. Supplemental foods have the added advantage of assisting in the cultivation of a taste for a variety of foods that later on are even more important in the diet. The smooth strained foods of early infancy may be gradually changed to coarser foods beginning at about six or seven months and to distinctively coarser foods soon after the baby is a year old. While it would appear that most babies tend to demand coarser foods voluntarily when given a choice, failure on the part of the mother to supply them sometimes results in the persistence of the desire for smooth foods long beyond the end of the first year.

It is important also to mention the fact that the parents' attitude toward foods is unquestionably recognized by infants at an early age. Thus it is very helpful for the parents to adopt the habit of regarding all good foods as pleasing and pleasant to eat. The opposite attitude often results in refusal on the part of the infant.

Water should be available at all times for drinking purposes and can be given at any time to satisfy thirst. Generally speaking it is desirable not to give water within 15 minutes before a regular feeding time.

A good working philosophy is to regard eating as a pleasure and not a duty. Well babies should never be forced to eat.

INFANT WELFARE: *see* INFANTS, CARE OF; MATERNAL AND CHILD HEALTH.

INFECTION: *see* BACTERIAL AND INFECTIOUS DISEASES; PARASITOLOGY. For infection in the sense of boils, abscesses, etc., *see* INFLAMMATION.

INFECTIOUS FEVERS: *see* CHICKEN POX; MEASLES AND GERMAN MEASLES; SCARLET FEVER; TYPHOID AND PARATYPHOID FEVERS; WHOOPING COUGH; etc.

INFECTIOUS MONONUCLEOSIS (GLANDULAR FEVER) is a common infection in man that has been observed in many parts of the world. It is probably caused by a virus. The disease occurs predominantly in persons from 10 to 35 years old but may appear at any age; it is rare in infants and young children.

Infectious mononucleosis is probably contagious, being transmitted primarily by oral contact with exchange of saliva. The incubation period is thought to be about 30 to 40 days. The commonest symptoms are malaise and sore throat. Enlargement of the lymph nodes in all parts of the body is frequent; those in the neck are most often affected. Fever of varying degree is usual. In some cases the only signs of the disease are fever and generalized discomfort; in these cases, the diagnosis is made by study of the blood. The throat is often red; a membrane, white to dark gray in colour and resembling that of diphtheria, may be present; ulceration of the pharynx occurs occasionally. There is a petechial rash on the soft palate in many cases.

In about two thirds of patients the spleen is enlarged; death has occurred in a rare case from rupture of this organ. A rash consisting of multiple small hemorrhages or resembling that of measles or scarlet fever sometimes appears. Pneumonia is present in about 2% of the cases. Involvement of the liver, as shown by chemical tests, is almost universally present; severe disease of the liver with jaundice is rare. Encephalitis, meningitis or peripheral neuritis occur uncommonly; death has followed the encephalitis. The heart is rarely affected. Swelling of the upper eyelids is a common finding. In rare cases, the urine may contain blood.

The disease is suspected when fever, sore throat and enlarged lymph nodes are present. A presumptive diagnosis is made from study of the blood. The white blood count is usually elevated but it may be low; there is an increase in the relative number of lymphocytes, a varying percentage of which appear abnormal. The number of eosinophils may be increased. In from two to seven weeks after the disease begins, there appears in the blood a substance (a so-called heterophil agglutinin) that causes clumping of sheep red blood cells. When the test for this agglutin is properly performed, the procedure is positive and diagnostic in about 95% of the cases.

Infectious mononucleosis usually lasts for about 7 to 14 days. In some instances it may persist for several weeks, especially when the liver or nervous system is affected. Relapse occurs uncommonly and second attacks are probably very rare. There is no specific therapy. Antibiotics are of value only for the secondary bacterial infections of the throat that occur in some cases.

INFERIORITY COMPLEX, a term used by some psychiatrists and psychologists, particularly the followers of Alfred Adler, to denote a feeling of inferiority that is wholly or in part submerged in the unconscious. The term "inferiority feeling" was used frequently by Adler, who held that many outstanding achievements, some antisocial behaviour and other continuing aspects of the personality could be traced to overcompensation for this feeling. The use of "complex" later gained acceptance to denote the group of emotionally toned ideas, partially or even wholly repressed, organized around and related to such feelings of inferiority. The term "inferiority complex" has lost much of its significance through imprecise, popular misuse—for example, as an attempt at a facile explanation of any show of ambition by a man of small physical stature. *See* ADLER, ALFRED.

(H. F. HT.)

INFINITE PRODUCTS, in mathematics, are products in which the number of factors is without limit. The capital pi, Π, indicates a product. Suppose $a_1, a_2, a_3, \cdots$ is a number sequence, m a positive integer, $\prod_{p=m}^{m}(1+a_p) = (1+a_m)$ and, if n is an integer greater than m, then

$$\prod_{p=m}^{n}(1+a_p) = (1+a_n)\prod_{p=m}^{n-1}(1+a_p).$$

If there is a positive integer m such that $\lim_{n\to\infty}\prod_{p=m}^{n}(1+a_p)$ is a number distinct from zero, then $\prod_{p=1}^{\infty}(1+a_p)$ is called an infinite product and its value is $\lim_{n\to\infty}\prod_{p=1}^{n}(1+a_p)$.

The infinite product has the value zero only in case a factor $(1+a_p)$ is zero. Also, there is a positive integer k such that $|a_p| < 1$ if $p > k$, inasmuch as

$$\lim_{n\to\infty}\left[\prod_{p=m}^{n}(1+a_p)\Big/\prod_{p=m}^{n-1}(1+a_p)\right] = \lim_{n\to\infty}(1+a_n) = 1.$$

Infinite products appear frequently in function theory. The infinite product for the Riemann zeta function is of great historical and considerable present importance in number theory (*see* NUMBERS, THEORY OF: *Topics in Analytic Number Theory*). In particular, infinite products form a basis for investigation of entire functions. A function f, that is not identically zero, having a power series representation $f(x) = \sum_{p=0}^{\infty} a_p x^p$, valid for every number x, is called an entire function. Any entire function having infinitely many roots may be represented as an infinite product. For example, $\sin \pi x = \pi x \cdot \prod_{p=1}^{\infty}(1 - [x^2/p^2])$, for every number x. If, in particular, $x = 1/2$, this gives Wallis' infinite product for the number π. The reciprocal of the gamma function, a generalization of the factorial, is an entire function given by the infinite product: $1/\Gamma(x) = e^{cx}x\prod_{p=1}^{\infty}(1 + [x/p])e^{-x/p}$, where $c = .5772\cdots$. These two facts reveal a relationship between the sine function and the gamma function, namely: $\Gamma(x)\Gamma(1-x) = \pi/(\sin \pi x)$. If $x = 1/2$ this gives: $\Gamma(1/2) = \sqrt{\pi}$.

There are several existence theorems for infinite products: (A) If $a_p > 0$, p = 1, 2, 3, $\cdots$, then the infinite product $\prod_{p=1}^{\infty}(1+a_p)$ exists if, and only if, the infinite series $\sum_{p=1}^{\infty} a_p$ converges. This follows from the inequality $\sum_{p=1}^{n} a_p < \prod_{p=1}^{n}(1+a_p) < \operatorname{Exp}\sum_{p=1}^{n} a_p$.

(B) If the infinite product $\prod_{p=1}^{\infty}(1+|a_p|)$ exists, then the infinite product $\prod_{p=1}^{\infty}(1+a_p)$ exists. Suppose $P_n = \prod_{p=1}^{n}(1+|a_p|)$ and $Q_n = \prod_{p=1}^{n}(1+a_p)$. Then, $|Q_{n+m} - Q_n| = |Q_n|\cdot\left|\prod_{p=n+1}^{n+m}(1+a_p)\right| - 1| \le P_n\left(\prod_{p=n+1}^{n+m}(1+|a_p|)\right] - 1) = P_{n+m} - P_n$ so that $\lim_{n\to\infty} Q_n$ exists. Suppose $c_p = -a_p/(1+a_p)$, $p \ge k$, where k is a positive integer such that $|a_p| < 1/2$ if $p \le k$. Since the series $\sum_{p=k}^{\infty}|c_p|$ converges, then the $\lim_{n\to\infty}\prod_{p=k}^{n}(1+|c_p|)$ exists and therefore the $\lim_{n\to\infty}\prod_{p=k}^{n}(1+c_p)$ exists. But the latter is $\lim_{n\to\infty}[1/\prod_{p=k}^{\infty}(1+a_p)]$ so that $\lim_{n\to\infty}\prod_{p=k}^{\infty}(1+a_p)$ is distinct from zero. This completes the proof.

Other theorems may be obtained by considering the logarithm of the partial product $\prod_{p=m}^{m+n}(1+a_p)$.

There is another kind of infinite product that is analogous to an integral and is called an integral product or continuous product. If each of f and g is a function on an interval $[a, b]$, the integral product $\prod_{a}^{b}(1+f\,dg)$ is a limit of products $\Pi(1+f(x)[g(q)-g(p)])$ taken for all intervals $[p, q]$ of a finite collection of nonoverlapping intervals filling up $[a, b]$, with x a number in $[p, q]$. For example, if I is the function such that, for every number x, $I(x) = x$, then $\prod_{0}^{x}(1+dI)$ is the exponential function E such that $E(x) = 1 + \int_0^x E\,dI$. This idea can be extended to large classes of differential and integral equations.

For a theory of entire functions, see E. Borel, *Leçons sur les fonctions entières* (1921) and R. P. Boas, Jr., *Entire Functions* (1954). Philip Franklin, *Treatise on Advanced Calculus* (1940), chapters IX and XVI, deals with infinite products. J. W. Neuberger, "Continuous Products and Nonlinear Integral Equations," *Pacific Journal of Mathematics*, vol. 8 (1958), deals with continuous products and contains references to earlier papers.

(H. S. WL.)

INFINITESIMAL originally meant a quantity less than any finite quantity. In dealing with non-negative real numbers, an infinitesimal must necessarily be zero; hence the use of the word in the calculus has led to much confusion. However, once the notions of limit and continuity were invented and the calculus was based on the real number system, the term infinitesimal was found to be unnecessary for the concepts of derivative and integral and has gradually begun to disappear from use. *See* CALCULUS, DIFFERENTIAL AND INTEGRAL. (I. M. S.)

INFINITESIMAL GEOMETRY, an alternate term for differential geometry. *See* DIFFERENTIAL GEOMETRY; GEOMETRY.

INFINITY AND THE INFINITE. These terms (from Latin *in-*, "un-," and *finis*, "end" or "limit") in common usage express our felt inability completely to carry out the procedures of counting, measuring, comparing, etc., by means of which size, number or degree can be assessed. Thus we say that there are an infinity of stars in the heavens or of colours on a bird's wing, that someone has been infinitely kind, etc. With this inability to assess go strong emotional overtones; the infinite usually astonishes, wearies or confounds us. In stricter contexts a predication of infinity implies a considered belief that the repeated

application of procedures of counting, measuring, comparing, etc., will always be demanded by the material on hand and will never lead to a final assessment of size, number or degree. Thus we say that there are an infinity of fractions between 0 and 1, implying that we shall always be able and obliged to discover new fractions between these limits. In more religious and metaphysical contexts, the notion of the absolutely infinite is developed, the idea of something whose size, number, degree, etc., cannot be assessed *in any respect whatsoever* and which is therefore omnicomprehensive and omnicompetent: this notion is obviously of greater difficulty and of more doubtful consistency than that of the simply infinite. We may note that there are always both positive and negative aspects to our notion of the infinite: a predication of infinity is, from one point of view, negative, being a confession of our inability to assess size, number or degree; but it tends also, from another point of view, to be regarded as a positive assessment, one demanded by the character of our object and one that is, in many respects, extremely hard to understand or to justify.

The Infinite in Ancient Thought.—Infinity appeared to ancient Greek thought in two contradictory guises. To the thinkers of Ionia it was attributed to the boundless environment of our cosmos and was an object of honorific assessment. Thus Anaximander (*q.v.*) set our world, together with countless other similar worlds, in a boundless environing material medium, "that becoming might not fail"; he also spoke of this medium in laudatory and religious terms. Even Melissus the Samian, whose notion of unchanging being was Italian rather than Ionian, felt obliged to hold that "that which is" was infinite in magnitude, while Anaxagoras (*q.v.*) of Clazomenae constructed his world out of an infinity of particles called "seeds," which were also infinite in variety and in "smallness." As opposed to this positive, favourable attitude to the infinite, the Italian attitude (represented by Pythagoras) was unfavourable and negative: the infinite was put into the class of things obscure, variable, unfinished and therefore bad. It stood in essential opposition to the "limit," whose work was the simplifying ratio or the precise mathematical proportion. The infinite showed itself in the "boundless breath" of darkness from which the starry units were separated, in the boundless variability of the crooked line or of the oblong as opposed to the constancy of the straight line or of the square, in the irrational and in the incommensurable of which the Pythagoreans (in search of a simple ratio between the diagonal of a square and its side) had had bitter experience. This unfavourable view of the infinite was passed on to Parmenides (*q.v.*) of Elea, who refused to make his unchanging being infinite "since it is in need of nothing, and since what is infinite is in need of everything"; and to Parmenides' disciple Zeno, who found a sufficient reason for denying that "things are a many" in the fact that, if such plurality were admitted, it would lead to the admission of an infinity of units between any two distinct points, and that such an infinity was not a number at all. Zeno also based his famous proofs of the impossibility of movement on the fact that it involves passing through and completing an infinity of successive stages.

This negative, Italian view of the infinite was adopted by Platonism, for which the infinite was essentially the irrational, flowing or formless principle, capable of indefinite increase and diminution which has to be subordinated to the "one" or the "limit" in order to give rise to whatever is intelligible and good. It is the indefinite element in the ideal world, which has to be bounded by the One in order to give rise to those precise, quantitative patterns with which Plato ultimately identified his "ideas." It is also the indefinite element in the world of the senses, whose bounding by numerical ratios gives rise to whatever is healthful, strong, musical or visibly excellent. In itself, however, it admits only of a contradictory characterization: it is essentially "the others," "the great and small." It shows itself, particularly, in the way in which quantitative parts evanesce into other parts without end and in the way in which a new beginning, middle or end always appears before, within or after any beginning, middle or end that we try to fix. (For Plato's attempt to describe the continuum, *see* his *Parmenides*. For further interpretation of his doctrine, *see* the works cited in the bibliography below.)

This mystical Platonic view of the infinite was replaced by the clear formulations of Aristotle, which have, to a large extent, remained definitive for western thought. For Aristotle the infinite exists only "after a fashion": after another fashion it does not exist at all. It never exists in the sense that we ever actually have an infinitely large number of things or of parts of things or anything which exceeds in size all things of limited bigness. The infinite is something potential or facultative: its presence in a field means that one always can go on to ever larger sizes, divisions or number in that field, that one can go outside of any given size or number to one that lies beyond it. So understood, the infinite is incompatible with wholeness and perfection; for something to be infinite means that one never can have all of it, only more and more of it. Mathematicians, Aristotle observes, talk as if they needed infinite quantities in their calculations; in reality they need only finite quantities, but as large as they require. Nor can our world contain anything infinitely great, since Aristotle shows it to be finite and spherical. It is not actually, but only potentially, infinite by division: this fact is used by Aristotle to refute Zeno's "disproofs" of the possibility of motion. Time, indeed, goes on endlessly in either direction, but it is not infinite in the sense of ever being there all at once. Even the potential being of the infinite is, for Aristotle, a queer sort of potentiality: unlike the potentiality of the statue in the block of stone, it can never be translated into actuality. (J. N. F.)

The Infinite in Theology.—The word "infinite" has been used in religious thought, both eastern and western, to designate one of the attributes of God and to express the whole nature of the divine; and indeed the expression "the Infinite" occurs as a name for the religious object, sometimes replacing the traditional term "God." Many meanings have been comprehended under the concept of infinity as employed by theologians: being without end or limit; being original and without beginning; being the inexhaustible source of all things; being indeterminate; being wholly self-determining; being incomprehensible and beyond the reach of human thought.

The theological use of infinity reflects the ambiguity found in Greek thinking about the infinite (apeiron) expressed in the different attitudes of the Pythagorean and Ionian traditions (*see* above). There was, on the one hand, uneasiness about saying that God is infinite because of the imperfection thus implied: what is infinite is unfinished and belongs to a lower order of things. When, on the other hand, infinity was understood as the original source or all being, implying the absence of limitation in power, truth and goodness, it became possible to speak of God as infinite.

Thinkers within the Judaeo-Christian tradition have long included infinity among the attributes or names of God. Among those accepting the term, two different lines of thought developed. Some held that the infinity of God is a negative concept serving to express the absence of limitation in the divine perfections and to indicate the inability of finite reason to comprehend the divine nature. Others have taken infinity as a positive concept expressing the inner nature of God rather than indicating the unendingness associated with the denial of limits. The first approach envisages a complete discontinuity between finite and infinite; the second seeks intelligible connections between them.

Philo of Alexandria, interpreting the Hebraic tradition in the 1st century A.D., understood the divine infinity as a positive perfection. Thomas Aquinas held that God is absolutely infinite, but, like many other medieval thinkers, he understood this in a largely negative sense. Henry of Ghent stands out in the 13th century for his claim that the infinity of God means more than a denial of limits. Nicholas of Cusa was influential in establishing the idea that infinity is the distinguishing mark of God and that finite and infinite are essentially related.

Spinoza and Hegel gave to modern religious thought the concept of the "true infinite" as the self-determining. In Hegel infinity became associated with subjectivity and self-consciousness. Hegel gave metaphysical expression to the tradition of German mysticism (Meister Eckhart and Jakob Böhme), according to which finite and infinite, man and God, are correlative. Instead of being for-

ever beyond the finite, the infinite is realized in man's experience of self-consciousness and self-transcendence. Kant was more cautious and denied that man is able to have theoretical comprehension of the infinite God on the basis of his finite reason. In much 19th-century religious thought, infinity signified the incomprehensibility of God, and it appeared more often as an expression of mystery than as a precise theological concept.

The charge has been made that the traditional infinity ascribed to God does not do justice to the reality of time, change and evil in the world. Some have proposed to substitute a "finite" God in order to solve the problem of evil. God is thus reduced to a being in the world.

A combination of German idealism and existential philosophy has produced theologies in which the infinity of God appears as complete self-transcendence; man is directed toward the real infinite God through the limited self-transcendence which he experiences in himself.

Major problems involved in speaking of the infinity of God are: first, that of giving some positive meaning to the concept—whether it be self-transcendence, according to Paul Tillich; or self-representation, according to Josiah Royce; or inexhaustibility, according to A. N. Whitehead—that will enable us to avoid taking it in a merely negative sense; secondly, that of distinguishing finite and infinite so that we can understand the difference between them while preserving their essential connections; and thirdly, that of showing the compatibility between the divine infinity and the reality of time, history and future creativity. (J. E. Sm.)

The Infinite in Modern Philosophy.—Modern post-Renaissance thought shows the same tension as does ancient thought between the acceptance of an actual and a merely facultative view of the infinite. In the main, the continental European rationalists espoused the former, while the British empiricists favoured the latter. Thus Descartes held infinity to be a positive notion: it is only by contrast with the infinity involved in my inborn idea of God that I can become conscious of my own finitude. In Spinoza the infinite becomes the omnicomprehensive or absolutely infinite: reality or substance is for him infinite in a sense which renders illusory any division of it into clear-cut finite parts and which entails its including not merely infinitely many finite "modes" but also all possible modes in each basic kind or attribute. In Leibniz, too, there is a ready acceptance of the view that in every organized part of nature there is an actual infinity of subordinate parts, each expressing a governing monad or entelechy. He is careful to explain, however, that (apart from God) he does not believe in a single substance which is infinitely great or infinitely small: the infinitely great and small (as employed by him in the calculus) are for him merely useful mental fictions not admissible in philosophy (*see* his letter to B. des Bosses, March 11, 1706). But if Leibniz had reserves in this regard, his contemporaries or successors had none: they talked without scruple about infinitely small or vanishing quantities and spent much time over such problems as that of the value of the infinite sum $1-1+1-1+1-\ldots$.

As opposed to this uncritical acceptance of an actual infinite, the British empiricists were more wary. Thus Locke spoke of our idea of infinity as an "endless growing idea" and denied, as against Descartes, that we could ever form a positive and distinct idea of infinite magnitude In like fashion Berkeley, in *The Analyst,* subjected contemporary mathematical treatments of the infinitesimal to a devastating critique. Hume, too, refused to allow that we had an impression, and could consequently form an idea, that admitted of the infinite division demanded by the mathematicians. It is this critical approach to the infinite which is, in the main, characteristic of the German idealists. Thus Kant gets round his antinomies involving infinite series—the antinomy, for instance, as to whether the world ever had a beginning in time or not, or as to whether its series of events goes back to a first cause or admits of an infinite regress in causation—by holding that, while we are obliged to go back indefinitely from any empirical feature of the world to other features presupposed as its conditions, it makes no sense to try to sum up the totality of conditions thus involved. For Kant as for Aristotle, infinity is incompatible with completeness. The same point of view is given a somewhat mystical expression by Hegel, when he contrasts his own "true infinite" with the "bad infinite" of the mathematicians, the bad infinite being characterized by an endless vain effort to transcend the finite, which it only succeeds in reinstating, whereas the true infinite is achieved when the finite is seen in its place in the whole system of finites, as expressive of a unity which pervades them all.

The Mathematical Infinite.—Modern mathematical thought has devised various conceptions which have enabled it to avoid confused and self-contradictory views of the infinite. Thus the useful phrases "tending to zero" and "tending to infinity" have been, since the time of Augustin Cauchy (1789–1857) (*q.v.*), so interpreted that they no longer seem to involve a reference to single quantities which are infinitely large or infinitely small. To say, for instance, that a certain function of a variable x "tends to infinity" as x "tends to zero" is merely to say that one can make the value of that function of x exceed any finite number, however large, provided that x is given a value sufficiently close to zero. In the same way, useful geometrical talk about points, lines and planes "at infinity" involves no reference to anything infinitely remote. Thus to say that parallel lines intersect at a point at infinity is only to say that the point of intersection of lines which are *not* parallel will recede to any finite distance, however remote, the more nearly such lines approach the parallel.

In another region, however, modern mathematical thought has tended to reinstate the actual infinite; *i.e.*, the field of Georg Cantor's transfinite numbers. This development rests on a view of number which connects it with the establishment of one-one correlations between the members of different classes and which applies this notion to the case of series or progressions which lack a final term; *e.g.*, the series of positive integers 1, 2, 3, 4, etc. If we now ask ourselves what number can be assigned to the whole set of terms belonging to such a series or progression, it will be plain that we cannot assign to it the number of any subset reached in the successive running through of such a series or progression. We shall have to widen our notions of number and assign to it a number differing from, and also exceeding, any such successively reachable number. It will have to be the number *of* an ordered progression lacking a final term, not any number exemplified *in* such an ordered progression. Though such a number cannot be reached through stepwise increases by unity (which Cantor calls his first principle of the formation of numbers), it can be reached by considering the whole set of terms which are reachable by such stepwise procedures (this Cantor calls his second principle of the formation of numbers). The functioning of this new type of number will be in many ways peculiar. Thus a transfinite aggregate will not be increased by the addition of a unit or by that of a finite number of such units: it can even have infinitely many units added to it or taken away from it, while remaining as infinite as ever. Thus the series of odd integers can be put into one-one correlation with the complete series of integers and is therefore of the same number. This capacity to have proper parts which are equal in number to the whole can be taken as definitory of transfinite aggregates. It can, however, be shown that not all transfinite aggregates can be put into one-one correlation with one another: there are some (*e.g.*, that of the real numbers in the continuum) which elude reduction to an ordered list or progression and which must therefore be said to be of a higher, nondenumerable type of infinity. The theory of Cantor deals with many distinct orders of nondenumerable infinity.

The Cantorian theory has built up an account of transfinite number in which no inconsistency is discoverable. There are, however, profound obscurities in regard to the precise meaning of the theory: it gives rise to problems deeply involved with questions concerning the foundations of mathematics and the analysis of numerical statements. On certain views (*e.g.*, the somewhat different views of Ludwig Wittgenstein and L. E. J. Brouwer), we can make use of the idea of infinity only in cases where we have a rule to guide us through its labyrinth: it is senseless to talk as if we could ever have an infinite aggregate before us or could ever complete a process involving an infinite number of steps or cases. Such views give small

meaning to Cantor's denumerable type of infinite and no obvious meaning at all to his higher, nondenumerable types of infinity. On other views, *e.g.*, that of Bertrand Russell, talk about the infinite involves us in finding some actual class somewhere in the universe, correlation with which will constitute the infinity of any class; such an "axiom of infinity" is, however, profoundly dubious, more particularly in view of the findings of modern physics, which make the world finite in extent and in divisibility. It may, however, be argued that there is no more to the "existence" of transfinite numbers than the *possible* existence of aggregates exemplifying any and every finite number in their proper parts, and that we perfectly understand what this means. On such a view, the main use of Cantorian concepts is to dispel the atmosphere of awe and mystery attaching to the mathematical infinite and to restore it to those ethical, aesthetic and religious objects to which it more properly belongs.

INFLAMMATION, in medicine, is a complex mechanism developed in the course of evolution as an adaptation to life on earth. In it are seen the fundamental attributes of life—response to stimuli, ingestion, digestion and synthesis of new material—organized to combat assaults and invasions of the physical and organic world. From amoeba to man, the mechanism increases in complexity with subdivision of functions among cells and the appearance of new chemical and morphological structures. Its operation, like that of all other mechanisms, has limits; if pushed beyond these limits, it will fail. And like all mechanisms, it can go awry and in doing so may produce disease. When it operates smoothly the mechanism of inflammation helps guarantee the individuality and integrity of an organism and facilitates the continuation of life.

General Pattern.—Some aspects of inflammation, such as pus formation, were recorded as long ago as the second millennium B.C. in Egyptian papyri. The gross manifestations, *rubor* (redness), *tumor* (swelling), *calor* (heat) and *dolor* (pain), were described in the 1st century A.D. by Celsus, who regarded inflammation as a disease in itself. Although Galen in the 3rd century A.D. hinted at the idea that the process could be initiated by injury, it was John Hunter in the 18th century who first clearly recognized that inflammation is the important common reaction of local tissue to any injury. The basic process of inflammation in higher animals can be divided into three parts: (1) blood vessel changes; (2) exudate formation; and (3) repair.

Blood Vessel Changes.—Much of the present understanding of the process of inflammation has come from microscopic and chemical studies of experimentally induced lesions. J. F. Cohnheim, a 19th-century German experimental pathologist, made use of transparent structures of the frog, such as the tongue, the webs of the feet and the mesentery. In order to excite inflammation he used such agents as silver nitrate or croton oil. With the microscope he observed the sequence of vessel changes that occur regularly after injury. The main change is dilation of vessels, sometimes preceded by transient constriction. The arterioles dilate first, then the veins and finally the capillaries. As this dilation occurs, blood flow in all the vessels becomes greatly accelerated. Following this, the rate of flow slows to less than normal, dilation of vessels persists and capillaries may become even more apparent. After some hours all vessels appear abnormally distended with blood; large numbers of white blood cells are seen in the peripheral layers of the flowing blood stream and adhering to the vessel walls. Clumps of erythrocytes are visible. In some vessels blood flow may stop temporarily. Adherence of leukocytes to the endothelium may persist for hours. After a mild injury, such as pinching or pressure, the blood flow soon resumes its usual pattern and adherent leukocytes return to the stream. Following more severe injuries the vascular alterations frequently persist and some vessels may become blocked (*i.e.*, thrombosed).

The Exudate.—The formation of an exudate, one of the characteristic features of inflammation, is related to alterations in the endothelium of the small blood vessels. An exudate is a colloid-rich accumulation of fluid usually containing cells and cell debris that appears in the locale of an injury. The bulk of its colloid and cell constituents derive from the blood; some may also be contributed by the tissue parenchyma. Normally only small amounts of plasma proteins appear in the extravascular fluid, but in inflammation there is an increase in the permeability of the walls of the small vessels. If a dye that attaches to the plasma albumin is injected into the blood stream and a local area of inflammation induced, an accumulation of the dye in and around the injury can be observed shortly.

As Cohnheim and others observed, the leukocytes of the exudate come largely from the blood. In preparations made by placing a transparent chamber in the ear of a rabbit, the migration of leukocytes into the areas of inflammation can be watched. After the stage in which leukocytes stick to the endothelium, these cells can be observed emigrating through the endothelium. By amoeboid motion the leukocytes pass through the vessel wall and into the space between tissue cells. The passage of leukocytes is probably between the endothelial cells. The speed of emigration depends on the nature and severity of the injury.

Although others had observed leukocytes in inflammation before him, the Russian zoologist Elie Metchnikoff (1845–1916) was the one who emphasized their importance as phagocytes; his series of comparative pathological observations is now classical. In simple transparent invertebrates without a circulatory system he observed wandering cells in the mesoderm. The mesoderm is the equivalent of mammalian connective tissue. When a foreign body penetrated the ectoderm of the animal the wandering cells surrounded it. When microorganisms entered the body cavity these amoeboid cells phagocytosed the organisms and digested them. If they did not do so the microorganisms multiplied and killed the host. He further pointed out that in higher animals the polymorphonuclear leukocytes, monocytes and eosinophiles of the blood, the macrophages of the tissues and the cells of the reticuloendothelial system perform the phagocytic functions. (*See* also PHAGOCYTOSIS.)

Repair.—Reparative phenomena, including proliferation of blood vessels and connective tissue, are a usual part of inflammation. Repair occurs not only following tissue destruction but also in some cases without microscopically visible tissue loss. In some inflammations, repair is the dominant feature. Capillaries originate by sprouting from existing vessels. Connective tissue fibres are produced by fibroblasts. Fibroblasts are probably formed mainly from macrophages and perhaps also from existing fibroblasts.

Explanation of Signs.—From what has been described thus far it is possible to obtain much of the explanation of the four cardinal signs of inflammation. Redness is due to the dilated blood vessels; swelling results partly from vessel dilation but mainly from exudate formation; heat is produced by an increased blood flow; pain is caused in part by local swelling and pressure and also by chemical

substances that are liberated in the process and act on nerve endings.

(*See* also BACTERIAL AND INFECTIOUS DISEASES: *General Features of Infectious Diseases;* PATHOLOGY: *Defense Reactions of the Body.*)

Varieties of Inflammation.—Although all inflammations exhibit a similar basic pattern, there are many variations. The designation acute is applied to inflammations of rapid onset and of a duration of up to several weeks. Chronic is applied to lesions of long duration, *i.e.*, of several months or more, and subacute is used to designate intermediate varieties. In the exudate of acute inflammations the polymorphonuclear leukocytes are most prominent. In subacute inflammations mixtures of cells including lymphocytes, macrophages and plasma cells occur along with some polymorphonuclear leukocytes. Chronic inflammations generally have a significant and large component of fibroblasts and their associated fibrils. Usually lymphocytes and other mononuclear cells are present in large numbers.

Patterns of inflammation vary also with different causative agents. For example, a local spreading, acute inflammation of the skin called erysipelas is caused by the β-hemolytic streptococcus. Characteristically the area is dusky red, swollen, hot and painful. The tissue cells are separated by exudate fluid containing the bacteria, some plasma proteins and a moderate number of leukocytes and erythrocytes. The small vessels are dilated. Tissue destruction is minimal. About nine days following onset, the lesion usually resolves as result of development of specific antibacterial antibodies that accelerate phagocytosis, digestion and removal of bacteria. Absorption of the fluid and colloids of the exudate occurs during resolution of the lesions. Phagocytes disappear and the ordinary pattern of vascular response is restored.

An abscess is an acute local inflammation frequently caused by staphylococci; pus is a characteristic feature. Pus is a form of exudate occurring in the centre of an abscess and comprising dead host tissue, many dead leukocytes and some living leukocytes. The semiliquid pus is surrounded by a fibrin network that has fluid and leukocytes in its interstices. Next to the fibrin is a layer composed of living tissue. From the vessels of this layer come the exudate constituents. In a chronic local abscess, a vascular connective tissue layer is proliferated and forms a capsule surrounding the pus. When the pus is evacuated from an abscess, healing occurs by new growth from this layer.

Introduction of particulate substances into tissues excites a foreign body reaction. Bits of talc or stone, sutures, splinters and glass, if not infected, excite only a mild acute inflammatory reaction with the characteristic vascular and exudative components. Most prominent is the appearance of mononuclear cells (macrophages) that surround and enguli small particles. Particulate material too large to be engulfed by single cells is frequently surrounded by multinucleated giant cells that arise either by fusion of the individual smaller phagocytes or by enlargement and nuclear multiplication of a single cell without division.

When an animal is invaded by certain organisms, such as the tubercle bacillus, granulomatous inflammation is the usual response. A military granuloma, called a tubercle, is the characteristic lesion of tuberculosis. Its centre comprises an avascular accumulation of mononuclear cells, called epithelioid cells, derived from monocytes. These cells contain tubercle bacilli. Intermingled with them may be a few multinucleated giant cells. On the circumference of the cell group is a network of fibroblasts infiltrated with lymphocytes. The centre of an area of tuberculous inflammation frequently is the site of caseation necrosis. This necrosis produces a cheese-like residue of dead host tissue. In a first infection with tubercle bacilli caseation takes several weeks to appear. Following a reinfection it appears in only a few days. This shortening of time is due to sensitization of tissues to products of the tubercle bacillus.

Allergy or immediate hypersensitivity reactions to antigens manifest themselves as inflammation. Two common examples are hives and hay fever. In hives, which are set off by ingestion or injection of the antigen, local areas of redness, swelling and itching appear. Microscopically the changes are those of mild acute inflammation with few cells in the exudate. In hay fever there is profuse secretion of mucus by the epithelium of the nasal mucosa as well as escape of fluid from vessels. Eosinophilic leukocytes are prominent in the cells present.

The injection of foreign protein antigens, *e.g.*, horse serum, in a sensitive individual can produce a severe local inflammation called an Arthus reaction (*see* ALLERGY AND ANAPHYLAXIS: *The Anaphylactic Reaction*). The Arthus reaction can also be produced by local injection of antigen-antibody complexes. Necrosis of the walls of blood vessels with infiltrations of leukocytes and thrombosis appear to be characteristic of this reaction. The process starts within minutes after injection and proceeds to its peak within hours. The fully developed reaction has a centre of dead tissue that is ultimately cast off and repaired by connective tissue.

Tuberculin-type, or delayed, hypersensitivity is another form that occurs when purified tuberculoprotein is injected into a person previously infected or immunized with tubercle bacilli. The reaction begins after an hour or more but takes two or three days to reach its peak. The early change is death of tissue cells (*e.g.*, epithelium and fibroblasts and vessel walls in the skin). In this instance the antigen-receptor and responding mechanism is associated not with circulating antibody but with tissue cells, including the mononuclear cells of blood and lymph.

Many special types of inflammation associated with particular organs are known. For example, meningitis, peritonitis and pleuritis are inflammations, respectively, of the surface membrane coverings of brain, gastrointestinal tract and lung. Myocarditis and valvulitis occur in the heart in rheumatic fever. Glomerulonephritis and pyelonephritis are two types of inflammation occurring in the kidney. Each of these is a special entity having characteristic causes and specific pattern variations dependent upon the causative agent, the organ affected and modifying factors in the host; yet all have the same basic pattern.

The Mechanism of Inflammation.—The sequence of vascular changes in inflammation is complex. Calibre and flow in blood vessels are controlled in part by the nervous system. Some of the early transient constriction and vasodilation may be due to a local nerve axon reflex, but inflammation follows its usual pattern even in denervated areas; therefore the bulk of the reaction must be mediated chemically.

A British physician, Sir Thomas Lewis, showed that histamine can reproduce the vasodilation and increased permeability associated with inflammation. When injected into human skin in minute amounts it causes the classical redness and swelling, but little or no sticking and emigration of leukocytes. Histamine is found in mast cells, which are frequently situated near blood vessels, and is released from these cells in inflammation. In mild inflammations, such as hay fever or hives, antihistamines will prevent or reduce the local reaction, but the vessel reactions in many inflammations are not inhibited by antihistaminics; therefore substances other than histamine must be involved.

5-Hydroxytryptamine, derived from the amino acid tryptophan, and also found in mast cells, causes reactions similar to histamine in some species. Certain polypeptides derived from interaction of proteins and enzymes can excite vascular reactions. Another agent known to increase permeability is a globulin of the blood plasma. Other constituents of cells may also operate. In addition, bacteria produce materials, *e.g.*, the erythrogenic toxin of β-hemolytic streptococci, that are capable of causing vasodilation.

Components of the causative agent and the host interact in the inflammatory process. Bacteria produce many substances: some are liberated from intact cells, some are liberated when the bacteria die. Staphylococci, for example, produce a coagulase that causes fibrinogen to clot. This fibrin clot acts as a minimal barrier to spread of infectious agents from the local area via tissue spaces and lymphatics. Other bacteria, streptococci and pneumococci, produce hyaluronidase, an enzyme capable of reducing viscosity of intercellular ground substance and thereby enhancing spread of fluid and particulate substances. The spreading inflammations caused by certain bacteria may owe this property to hyaluronidase or other spreading factors. Lecithinases, collagenases, proteolytic enzymes and enzymes that split nucleic acids are all produced by

bacteria. Each plays a role in the chemical dynamics and manifestations of inflammation. Some are excitants and others may inhibit parts of the process.

Mechanical injury, corrosive chemicals, bacteria and antigen-antibody complexes all excite inflammation by injuring tissue cells. Substances liberated from dead and dying cells stimulate the inflammatory response. Some of the liberated substances are polypeptides derived from the splitting of cell proteins, some may be amines from injured mast cells and perhaps some are derived from the breakdown of nucleic acids. In the Arthus reaction, antigen-antibody complexes have been demonstrated in the subendothelium of the venules. Antigen-antibody complexes associate with complement, which has enzyme activities. The antigen-antibody-complement complex together can lyse cells and initiate inflammation. Much of the mechanism of inflammation appears to involve enzymes and some inflammation can be partially suppressed by enzyme inhibitors.

Several mechanisms have been proposed to explain the passage of plasma colloids and the permeation of leukocytes and particulate substances through endothelium. Some investigators have deduced that pores present in the vessel lining are just large enough to permit plasma proteins to pass. No pores of this size (about 40 Å) have been seen with the electron microscope but observation with the electron microscope has revealed passage of particles through endothelial cells enclosed in small vacuoles. This mechanism is known as pinocytosis. A third mode of passage is via the spaces between endothelial cells. In inflammation, particulate substances (and presumably soluble colloids and fluid also) traverse the widened spaces. Leukocytes of all types, after adhering to endothelium, migrate through these spaces. The specific substances and the chemical mechanism involved in adhesion of leukocytes to and emigration through endothelium are unknown. In an area of inflammation leukocytes are attracted to bacteria; once in contact with the bacteria they engulf or phagocytose them. Within the intracellular vacuole formed during phagocytosis, death and digestion of the bacteria usually occurs. The substances responsible for killing and digesting are the granules of leukocytes. These contain many agents including histone, an enzyme called lysozyme and phagocytin—all with bactericidal capacity. Other enzymes of leukocytes granules are phosphatase, peptidase, peroxidase and nucleosidases. When phagocytosis occurs the granules disappear; their enzymes are released within the cell and enter the digestive vacuole. The optimum activity of many of these enzymes occurs in an acid medium and the vacuoles, as a result of partial metabolism within the leukocyte of glucose to lactic acid, usually have an acid reaction. Mononuclear leukocytes also have enzymes, including esterases and lipases. These, too, participate in intracellular digestion. When leukocytes disintegrate, the end products of digestion and their enzymes are liberated into the area of inflammation, where they operate locally to liquefy pus, to perpetuate the vascular reactions and perhaps to stimulate repair.

Modification of Inflammation.—In lower animals that lack blood vessels, inflammation is manifested only as a cellular response by migration, phagocytosis, cell secretion and repair. Higher forms have a complex blood vascular system and with it can direct specialized defensive cells and chemical substances to the area of injury.

With higher specialization have come other control mechanisms, such as nerve and endocrine systems. Endocrine hormones of the adrenal glands can modify inflammation. For example, local injection of epinephrine (adrenaline) can briefly suppress the hyperemia and part of the exudative component. The adrenal cortical hormone, 17-hydroxycortisone, will depress all phases of the inflammatory response for extended periods. When the agents of injury are not viable virulent bacteria, these hormones form a useful part of treatment, but in bacterial infection suppression of all or part of the inflammatory response can be deleterious.

The jeopardizing effects resulting from the absence of key elements in inflammation are seen in certain individuals. For example, some persons hereditarily lack the capacity to produce antibodies. These people are unusually susceptible to infection. In agranulocytosis, in which there is a deficiency of circulating leukocytes, there is decreased resistance to infection. Inflammatory lesions in such states show hyperemia and tissue necrosis without pus. Another peculiarity exhibited by some individuals is a hypersensitive inflammatory mechanism that responds in an exaggerated way to what in others are mild stimuli; such reactions are shown by sufferers of hay fever and, perhaps also, of rheumatic fever and arthritis.

INFLATION AND DEFLATION. The terms inflation and deflation have strong emotional connotations, and their loose and varying use often causes confusion. Both of them are usually employed to describe situations that are regarded as undesirable. Inflation is often used to denote price rises in their most marked and disagreeable forms and deflation frequently indicates not only declining prices but also falling business activity or unemployment on a large scale. Those writers whose use is most precise define the terms as relating to movements in the general level of prices.

Definition and Measurement.—At any one time prices of various goods and services are moving differently; some move at faster rates than others, either upward or downward. The general price level is an average or central tendency, and its changes describe only one feature of the great variety of individual price movements. Nor is the general level of prices an altogether clear concept since, as an average, it is expressible only in terms of an index number. Even if it were perfectly clear it would not be desirable to equate every rise or fall in the level with inflation or deflation. Such a procedure would carry the implication that inflation existed if the price level rose slightly from one month to another, and that a period of some years was inflationary if the price level at the end was a little higher than at the beginning. The concept of inflation and deflation should not depend on a fine calculation as to whether price rises outweigh price falls or not.

Inflation or deflation cannot be defined more precisely than as an increase or decrease of more than an acceptable minimum amount in an acceptable index of the general price rise. There is a considerable range of choice as to the type of index to be used. If it is to measure inversely changes in the value of the monetary unit, the index should include representations of all prices of goods and services on which money is spent. Such a breadth of coverage in a "transactions" index is never attained in practice. The nearest approach is provided by a price index of final output, *i.e.*, of goods and services, home-produced or imported, available for consumption, investment or export in the private or the public sector of the economy. More commonly, however, a narrower index is taken: a price index for all consumers' goods and services. Inflation and deflation are then regarded from the point of view of the final consumers and of the value of money to them. (*See* INDEX NUMBERS.)

Modern History.—In the 100 years before 1914, the movement of prices followed somewhat similar trends in the main industrial countries. Prices declined until about 1830, moved around

a level trend until the early 1870s, fell again until around 1895 and then rose in the period before World War I. Deflation on a modest scale was the rule rather than the exception; there was general inflation only in the last 20 years of the period and it amounted to no more than 20% in all. Even in the short run, over a few years, major inflations were usually followed by corresponding deflations and occurred only in association with massive expansions in the quantity of money created to finance government expenditures during and immediately after wars. The main examples are the severe inflation in the United States in the early 1860s during the Civil War and that in Europe after 1870 arising from the Franco-German War. In Great Britain prices rose by 10% between 1870 and 1873. (*See* PRICE.)

The period from 1914 to 1949 was dominated by major inflations caused by World Wars I and II and by severe deflation in the early 1920s and during the great depression of the 1930s. The most spectacular inflations of the runaway type occurred in central and eastern Europe after World War I. Productive capacity was largely destroyed in the defeated countries and the need for great expenditures on reparations and rehabilitation led governments to resort to the printing presses. Once started, the inflationary spiral was given extra spins by the general loss of confidence, by the breakdown of tax collection and by the widespread disruption of business as speculation replaced productive activity. In the great German deflation after defeat in World War I the circulation of paper marks reached astronomical figures by the end of 1923, when such an ordinary matter as the sending of a local letter cost 100,000,000,000 marks in postage. Inflation on this scale required major currency reform before confidence could be re-established. The German reichsmark of 1924 meant a complete repudiation of the previous paper currency.

The deflations of the 1920s and 1930s had no counterpart in the 15 years after World War II. On the contrary, after the widespread currency devaluations of 1949, inflation continued in most countries, usually on a modest but persistent scale. A new problem for governments arose, unknown in the previous 150 years of industrial growth, that of framing economic policy to maintain a high level of employment, and an economic activity near capacity, while avoiding a continual rise in prices. It was this problem which, in one form or another, dominated economic thinking in the 1950s and early 1960s.

Causes and Consequences.—Until the 1930s, inflation had been generally regarded as an infrequent problem, but a major and sometimes catastrophic one when it did arise. During inflation prices increased and the value of money declined at such a rapid pace as to disturb all previous trends. It was a situation in which there was an abnormal increase in the supply of money without a corresponding expansion in the volume of goods and services available: too much money chasing too few goods. The growth in the quantity of money was the cause, the rise in the price level an inevitable effect. No important inflations or deflations had in fact occurred for more than 100 years before 1930, except as a consequence of a war and of the resulting need to finance large government deficits. The creation of new money by the government could proceed in various ways but always with the same effect. The inflationary process is not much different if the government simply prints more paper currency, or if it borrows from the banking system and so creates new bank deposits.

One reason, and probably the most powerful, for the infrequency of major inflation or deflation before the great depression of the 1930s was the widespread use of the gold standard. This system limited the issue of paper money and bank deposits to the level which the public, able to exchange money freely for gold, was willing to hold instead of gold. Free gold convertibility under the gold standard proper, or a fixed money-to-gold ratio set by legislation as an alternative, was almost completely effective (except when abrogated in wartime) in setting limits to the power of governments to acquiesce in inflation. However, during the 1920s, it became increasingly the view that a rigid metallic system, for all its advantages, hindered economic progress. Increasingly, governments asked for and were given discretionary powers of control over the supply of money. For example, there was in Great Britain the unpopular return to the gold standard in the 1920s and the early failure of the move.

The experience of the great depression and the growing influence of the work of Lord Keynes in the 1930s led economists to take a different view of inflation. Moderate changes in the price level, both in the short run and over longer periods, were described as inflationary or deflationary, quite apart from variations in the supply of money. Emphasis was placed rather on decisions to consume and to invest out of income. An excess or deficit of planned expenditure over capacity to produce could lead to wide variations in the level of output and of prices. The relation of inflation and deflation on the one hand to over- and under-employment, to boom and depression on the other, is both important and complex, not direct and simple. Prices, employment, wages and profits are interrelated and it is not easy to measure these relations or even to specify the sequence of changes among the variables during inflation and deflation. The complicated nature of the problem was already clear by the end of the 1930s and it became increasingly urgent to find solutions as the policy of full employment took precedence in the politico-economic field, following World War II and particularly in the 1950s and early 1960s.

Even in the 19th century falling prices were generally associated with quite high levels of unemployment. Under the conditions prevailing from the middle of the 20th century onward, strong deflationary measures were likely to reduce output and employment more than prices. Modern business was almost as strongly opposed to price cutting as organized labour was to wage reductions. Political and economic pressures for expansionary measures were strong and governments found the line of least resistance along inflationary paths. It was quite generally agreed, moreover, that a moderate rate of increase in prices stimulated output and employment when an economy was operating below capacity. It was less clear whether the social dangers of serious inflation as full employment was approached offset the fact that business thrived on inflation at a moderate pace. Similar analyses of the situation could lead economists to different conclusions according to where they placed the emphasis. If the avoidance of underemployment took priority, an economist might prefer a continual rise in the price level, taking the risk that inflation accelerated as full employment was achieved and that continued use of inflation might tend to destroy its effectiveness. On the other hand, if the dangers of rapid inflation were to be avoided, he might prefer a check on rising prices, at the risk of some underemployment of resources at times.

The need for statistical and quantitative assessment of inflationary and deflationary processes, as opposed to a qualitative analysis, was apparent in the 1930s and urgent by the 1950s. Early work aimed at a system of relations completely describing the economy, including explanations of wage and price movements, and with particular reference to business cycles. Such a system for the United States was published by J. Tinbergen in 1939 and it was later developed by L. R. Klein. Subsequent British studies by A. W. Phillips and R. G. Lipsey and by L. A. Dicks-Mireaux and J. C. R. Dow, at the end of the 1950s sought for the determinants of inflation and, in particular, for economic models explaining the rate of change of wages. The feature of the 1950s examined was the continued rise in prices and wages despite quite considerable variations in business activity. Such recessions as those of 1952 in Great Britain, of 1954 in the United States and of 1958 in both countries could be described as deflations only in the sense that the rise in prices and wages became slower as output and employment declined. Two views of the increase in wage rates were advanced, roughly the "demand-pull" and "cost-push" interpretations. More precisely, one influence on the rate of change of wages is excess demand, making its impact in the labour market through less unemployment and more vacancies; another influence is that of the past rate of change in the price level on current wage determination and the consequent effect through higher costs on future prices. Both influences would seem to be important though with varying weights at different times since the middle of

the 19th century. *See* also CURRENCY; MONEY; WAR FINANCE; and references under "Inflation and Deflation" in the Index.

INFLORESCENCE generally means a flower cluster, but specifically refers to the arrangement of the flowers on the floral axis. *See* FLOWER: *Position of Flowers on the Plant: Inflorescences.*

INFLUENZA is an acute infectious respiratory disease caused by a virus. The disease commonly occurs in epidemics; they develop quickly, spread rapidly to as much as 25% to 40% of the population, with low fatality, and terminate abruptly. Within a short period of years the illness reappears in the same geographic area. It is abrupt and of brief duration, characterized more by prostration and aching than by obvious signs of respiratory disease. Complications of bronchitis and pneumonia are common. At times the epidemics become world-wide or pandemic, and during these periods, as in 1918, the severity of the disease and the frequency of complications may attain terrifying proportions. Some authorities have considered the severe pandemics a different disease from those of intervening years, but the resemblances between the two are so great as to suggest that they are of the same basic nature. The specific cause of epidemics previous to 1933 was not known. After that time, however, viruses (*q.v.*) were identified as the primary agents of influenza A and influenza B. Swine influenza, studied extensively by R. E. Shope, is caused by a virus related to type A influenza virus, in conjunction with a bacterium, *Hemophilus influenzae*.

History of Epidemics.—Influenza has a long history. An epidemic described by Hippocrates in the 5th century B.C. has been called influenza, but the first clear description is that of the epidemic of 1610. The descriptions of numerous outbreaks through the succeeding centuries reveal a tendency to surprising uniformity of behaviour but considerable variation in time of occurrence and severity. The severer outbreaks have been the most completely described, culminating in the extensive reports of the pandemics of 1889–90 and 1918.

Many of the epidemics were thought to have arisen in Russia, where a reservoir of influenza was said to exist and to have spread into Europe by the routes of travel. As rates of travel increased it became more and more difficult to trace a progressive extension until in 1918 the disease seemed to erupt almost simultaneously in widely separated geographic areas. In Oct. 1889 influenza was recognized in Siberia; in November it had reached Germany and France, and in December extended to Spain, Italy and England. In the same month the cities of the Atlantic seaboard of the United States were involved; in early January the cities of the middle west and, somewhat later, San Francisco, Calif., on the Pacific coast, had their peaks of incidence. In the autumn of 1918 much of the northern hemisphere was blanketed by influenza in approximately one month. Australia and certain rather isolated areas were not affected until later. These examples clearly illustrate the rapid, widespread distribution of the severe outbreaks; evidence indicates that in its milder forms the same tendency exists.

Epidemics of influenza commonly affect a high percentage of the population although accurate data have been uncommon. In pandemic times incidence rates as high as 30%–40% were repeatedly reported; in milder epidemics estimates of 10% were common. The frequency of illness is greatest in children, although the impression widely prevails that adults are most commonly attacked. It is true, nevertheless, that young adults are prominently affected.

Despite the high incidence, mortality is commonly low, and deaths from uncomplicated influenza are infrequent. On the other hand, there is usually an increased mortality from complications such as pneumonia, and excess mortality among patients with cardiac or other debilitating disease, especially at ages over 50 years. The 1918 epidemic was the most destructive in history; in fact it ranks with the plague of Justinian and the Black Death as one of the severest holocausts of disease ever encountered. It was estimated by E. O. Jordan that more than 20,000,000 persons perished of influenza in a few months and more than 50 times as many were sick. In India 12,500,000 persons, or 4% of the total population, are said to have been killed by influenza in the autumn of 1918. In the United States 548,000 died. In contrast, the pandemic of 1889–90, which also had a high attack rate, had a mortality of less than one-tenth that of 1918.

Influenza is most commonly a disease of the colder half of the year, but it is not strictly limited. The severer episodes appear to be less controlled by season than those of intervening years. In tropical and subtropical areas, epidemics occur with a frequency similar to that seen in the temperate zones.

Another feature encountered prominently in the pandemics of 1889–90 and 1918, as well as in earlier ones, is the tendency toward "waves" of infection. This is seen by the appearance of an epidemic, the first wave, in the winter of 1889–90; the second wave, a severer episode, 14 to 15 months later in the spring of 1891; a third mild disease in the late fall and winter of 1891–92. A mild, world-wide epidemic in the spring and early summer of 1918 was followed by the astoundingly severe epidemic in the autumn; a third rise in the spring of 1919 was quite irregular and was of doubtful relation to the preceding two. Reports are confusing as to whether an attack in the first wave gave resistance to the second.

Later Epidemics.—In 1933 influenza virus, type A, was first isolated by W. Smith, F. W. Andrewes and Patrick Laidlaw in London, and the following year in the U.S. by Thomas Francis, Jr. Thereafter a number of outbreaks of influenza A were observed at intervals of two to three years. There was variation in the extent of the epidemics; some were extremely mild and irregularly encountered, but those of 1936–37 and 1940–41 spread throughout the world. In most instances the influenza A epidemics were sharp and brief, beginning in the late autumn or winter of the temperate zones, while areas such as Hawaii and the West Indies were often affected earlier. Data of the percentage of population attacked are inexact, but 8% to 15% appears to be a reasonable estimate in the more clear-cut epidemics. It was shown, however, that the disease may be encountered in small, localized, almost sporadic outbreaks which sometimes precede the epidemic wave. The mortality has been low; scarcely 1 case in 1,000 was fatal. Nevertheless, an excess in mortality from pneumonia and in the general mortality accompanies the disease.

Influenza B was first identified in the U.S. in 1940 by Francis, who demonstrated also that an epidemic in that country early in 1936 was caused by the same virus. It also gave rise to an extensive epidemic in 1945. Influenza B seems to have been more scattered in its distribution, and the epidemics, which recurred at intervals of four to five years, were less sharply defined in scope. The incidence tends to be somewhat lower than with influenza A, and the accompanying mortality is proportionately reduced.

In some epidemics a proportion of cases have not been identified as influenza A or B, but no definite epidemic has been observed which might be attributable to still another type of influenza. Swine influenza virus has not been reported in the human population. The fact that these two types recur at intervals of a few years offers a possible explanation of the so-called three waves of a pandemic period.

It seems likely, with the appearance of these diseases in the northern and southern hemispheres in alternate halves of the year and with the recognition that they may exhibit limited, spotty tendencies, that influenza is maintained by a constant circulation in the human population, reaching epidemic proportions only when a sufficient number of susceptibles has reaccumulated to furnish fuel. (*See* BACTERIAL AND INFECTIOUS DISEASES: *Virulence.*)

Chronic carriers of the virus have not been demonstrated. Under this interpretation the severer pandemics represent variations in scope of a basic disease and may be related to the circulation of modified strains of virus and to the frequency and virulence of bacterial accompaniments. Laidlaw suggested in 1936, and the suggestion was supported by Shope, that swine influenza represents the human disease of 1918, which became established in hogs and persisted there. Shope presented evidence that the swine disease is maintained in a concealed form in worm parasites of that animal from which it erupts when the animal's physiology is disturbed.

The idea that there are geographical foci in Russia and the east in which influenza is maintained is a similar concept of a limited reservoir.

The epidemic of Asian influenza of 1957 apparently began in China early in the year. It was detected in Hong Kong among refugees early in April and extended soon to Singapore and Formosa (Taiwan). From there the distribution became quite wide and by June 10 the disease had circled the globe. Its course was readily traced along lines of transportation and numerous foci were described developing from affected groups.

The incidence was high, particularly in crowded areas of the orient; it was generally mild although, as usual, an increased mortality from respiratory disease took place. It appeared that the highest frequency was in adolescents and in people generally under 30 years of age.

In the United States a distinct increase in respiratory disease was noted beginning in August; the peak, both of incidence and excess mortality was reached by the end of October, after which a progressive decline took place. A significant proportion of the deaths apparently was associated with staphylococcus, and also cases of rheumatic heart disease with mitral stenosis.

The severity of the disease was reported to vary somewhat in different countries, but experience generally was that of a mild illness with high incidence and low mortality. In all regions crowding appeared to have been a significant factor in morbidity.

The virus, belonging to type A influenza virus, exhibited antigenic characteristics different from those of recent years, but serological evidence indicated that it is related to strains circulating earlier. Sera from the older segments of the population contained antibodies to the strain, suggesting that it may possibly have been prevalent in the 1889–90 pandemic period.

Intensive efforts were made in the United States in 1957, through the collaboration of all agencies concerned, to prepare for the epidemic. Large-scale production of specific vaccine was instituted and became available in significant amounts before the epidemic developed. Data indicated that with the proper concentration of virus, protection of 80% could be obtained. Much illness and mortality were prevented by widespread use of vaccine.

Etiology.—The name influenza was introduced by John Huxham in 1743, apparently derived from the Italian phrase which ascribed the origin of the disease to *un influenza di freddo*, the influence of the cold. It was not until 1890 that the idea that influenza was borne by the prevailing winds was dispelled. In 1892 Richard Pfeiffer described the influenza bacillus, *Hemophilus influenzae*, commonly a tiny organism, but of varied forms, which requires for its proper growth substances present in blood. Subsequent studies appeared to support Pfeiffer's conclusion that this organism was the cause of influenza. The pandemic of 1918 resulted in extensive studies of its role. It was generally concluded that while this organism was of considerable importance, perhaps greater than that of other bacteria, it did not satisfy the requirements of a primary causative agent. The concept of a filterable virus gained in prominence, and as a result studies in England, France, Germany, Japan and the United States were made in an effort to transmit the disease to human subjects and experimental animals. Results were quite variable, and, even in instances which were apparently successful, no agent was well established. As a result the cause of that epidemic was not clearly demonstrated.

In 1931 Shope demonstrated that swine influenza, hog flu, was caused primarily by a virus which in conjunction with a bacillus similar to that of Pfeiffer's produced extensive disease in hogs throughout the United States.

In 1933 Smith, Andrewes and Laidlaw produced an experimental infection in ferrets with a virus from the throats of influenza patients. This was confirmed in 1934 in the United States by Francis. It was then found that the virus infection could be transmitted to mice. In both species of animals continued transfer gave rise to extensive fatal, nonbacterial pneumonia. The virus produced infection only when given by the respiratory route. Animals which recovered were immune for a period of months to reinfection, and their blood serum contained immune substances (antibodies) capable of protecting normal animals. It was shown that a high percentage of the human population had immune bodies in the blood as a result of earlier infection and that the recovered person developed more. This fact could be used for diagnosis and studies of the distribution of the disease, designated influenza A. After 1939, following studies of F. M. Burnet, the incubating egg containing the embryonic chick was an increasingly effective tool for isolation of virus and studies of the disease. G. K. Hirst, L. McClelland and R. Hare observed that influenza virus caused clumping of the red blood cells of chickens and that the phenomenon could be applied to the measurement of virus and antibodies.

The virus of influenza B was isolated in 1940 by both Francis and T. P. Magill. Its general characteristics are similar to those of influenza A. It is, however, more difficult to establish experimental disease in ferrets, mice and frequently in eggs than with type A virus. Moreover, infection with one gives no immunity to the other, so that in this sense they represent two different diseases. The strains of type A or of type B also differ among themselves. Swine influenza virus is related to type A.

Infection does not give permanent immunity, but in experimental animals it can be renewed by reinoculation. In the general population there appears to be a decline of immunity between epidemics and thus an increase of susceptibles. Even after induced infection under experimental conditions the immunity may be of only a few months' duration. However, a good percentage of the population develops a resistance effective for a much more prolonged period, as shown by the fact that only a minority takes sick during epidemic periods.

Clinical Features.—Influenza spreads through a population by the transfer of virus by sneezing, coughing, etc., of the excretions from the respiratory tract of the infected person to that of a susceptible. In the majority of instances the process is a direct infection, although indirect transfer through contamination of hands, handkerchiefs or eating utensils is obviously possible. There is little reason to consider the disease air-borne except in crowded, poorly ventilated quarters when contamination of the air may be marked. As the virus gains entrance to the respiratory tract of the susceptible, it selectively attacks and destroys the cells lining the respiratory tract. These cells are superficially situated, not intimately bathed in the fluids of the blood stream, and apparently protected to a great extent by their own physiologic mechanisms. Following injury of the cells, fluid from the blood is poured out, and the supporting tissues give evidence of acute, inflammatory changes. The changes are essentially limited to the nose and the larger respiratory passages. When pneumonia ensues, the type of subsequent injury will depend upon the character of the bacteria encountered. If the pneumonia is related to virus infection alone, which is uncommon, the injury is usually an extension of that previously mentioned with a considerable amount of fluid accumulating in the lungs, areas of collapse and a few cells of a large type. Specific changes in other organs are not ordinarily observed although toxic effects are evident.

Symptoms and Clinical Course.—The incubation period of epidemic influenza is one to two days. The majority of cases present a striking uniformity of symptoms and clinical course. The onset is abrupt with sudden chilliness or distinct chill, fatigue and achiness. Severe prostration is noted early. The temperature rises rapidly in 12 to 24 hr. to a level of from 101° to 104° F. Diffuse headache and severe muscular aches throughout the body become prominent features. Whereas the patient may experience a feeling of nasal irritation or a sense of rawness in the nasopharynx,

symptoms referable to the respiratory tract are few. In this respect the disease is sharply different from the usual common cold in which congestion and runny nose with little or no fever are customary. Sore throat similar to that of acute tonsillitis is rare. In the next 24 hr. the temperature reaches a sustained level. Aches and pains may be the chief complaint. Laryngitis and hoarseness may be present and a short, hacking, unproductive cough may become annoying. Symptoms referable to the gastrointestinal tract are ordinarily no more common than in other acute upper respiratory infections, and the so-called intestinal flu is a misnomer. A nervous form has been described which seems to be essentially a designation of the severe prostration or delirium which may occur.

In three to four days as the temperature begins to fall the patient's general symptoms improve and recovery from the acute phase begins. In 90% to 95% of the cases, even in the severest outbreaks, the disease is a "three-day fever" followed by relatively rapid convalescence; but protracted weakness and exhaustion in adults are traditional. In children, except infants, the disease is generally mild, while in older persons it is severer than the average. When the temperature remains elevated beyond the fourth or fifth day, involvement of the lower respiratory tract is usually present and is ordinarily evidence of complications resulting from associated bacterial infection.

In addition to the usual course of the disease, a number of cases present a much severer infection from the onset. In these there is early evidence of respiratory distress and pulmonary disease. The course is stormy and unpredictable. On the other hand, there is a large group of cases in which the evidence of infection is negligible. These patients may experience nothing more than a mild apathy and a slight discomfort in the upper respiratory passages for a period of 24 hr. The temperature is either not elevated or elevated slightly. In others the symptoms may be so slight as to be unnoticed. Nevertheless, these inapparent infections constitute a serious menace in that they can transmit infection. In some instances, by appropriate tests it was shown that during the course of an epidemic 20% to 25% of persons were actually infected with influenza virus without significant signs of illness.

Complications.—By far the greatest number of and most important complications of epidemic influenza involve the respiratory tract. The various forms of bronchitis and pneumonia may ensue, and in some instances pneumonia apparently begins with onset of the disease. They are usually associated with invasion by pneumococci, staphylococci, *H. influenzae* or other bacteria which invade the lungs. In the U.S. army camps in 1918 purulent or capillary bronchitis was observed in as many as 35% to 40%, and pneumonia occurred in 10% to 20% of the cases. The incidence of complications varies in different epidemics; it is usually low but the frequency may depend upon the amount of virulent bacterial infection prevalent at the time. Paranasal sinusitis is not uncommon. Otitis media similarly occurs. Influenza acquired during pregnancy often results in miscarriage or abortion. There is consequently an increase in both maternal and infant mortality. In many respects influenza is one of the most dangerous complications of pregnancy.

Treatment.—There is no specific treatment for influenza virus infection. Drugs are used to relieve discomfort or control fever. Confinement of the patient to bed in a warm room conserves his resources and limits the possibilities of complicating infections. Although sulfonamides, penicillin and streptomycin have no effect upon the virus disease, they do have a therapeutic, possibly some prophylactic, effect upon the bacterial pneumonias which are the chief causes of death.

Control.—The continued recurrences of influenza clearly demonstrate that there has been no effective procedure for control. Rigid isolation may limit infection under special conditions. But under epidemic conditions the amount of infection to which the person may be exposed and the high infectiousness of the virus clearly nullify minor precautions. In the presence of virulent influenza, crowding may increase the risk of picking up secondary infections as well.

Efforts to control respiratory disease through sterilization of the air by installations of ultra-violet light or by bactericidal vapours (aerosols) were investigated.

Prophylactic Inoculation.—The fact that influenza virus produces disease only when it enters the body by the respiratory tract led to the demonstration that if given subcutaneously or by other routes, illness did not occur in animals or humans but that in the former a resistance developed and in both the accumulation of immune substances in the blood was stimulated. Various studies were undertaken to ascertain the effect upon susceptibility to the natural disease with no more than suggestive results.

The ready growth of influenza virus in the chick embryo results in the accumulation of virus in the allantoic fluid surrounding the embryo. This has served as a bountiful source of virus for vaccine. In 1943 the commission on influenza of the U.S. army epidemiological board carried out studies with a vaccine of virus concentrated from the egg fluid. The virus was obtained from the fluid by permitting it to become attached to the red blood cells of the chicken and then removing it into a reduced volume of sodium-chloride solution. The virus was inactivated by treatment with formalin. Both type A and type B influenza viruses were incorporated into a dose of one cubic centimetre to be given subcutaneously to adults. The results of the study showed that the incidence of influenza A in a vaccinated group of 6,250 men was about one-fourth that observed in a similar group of unvaccinated men. In 1945 the entire U.S. army was vaccinated with this material. Observations during the epidemic of influenza B that winter showed that 1% or less of vaccinated army personnel took sick while 10%–13% of unvaccinated service groups were affected.

The duration of resistance induced by vaccination is not known. It seems improbable that available preparations would have a uniform effect beyond three to four months. The antibodies developed from vaccination reach their peak in two weeks, decline somewhat in four months and still further in one year, but it is not established that the resistance is retained to the same extent as the immune substances. Moreover, the strains of virus encountered in different epidemics vary in chemical constitution, and this may limit the efficacy of vaccine until more strains or a collection of suitable ones are placed in the vaccine. Nevertheless, the information points to the probability that prophylactic vaccination would be effectively developed for use in the control of influenza—a disease which has been called the last of the unconquered scourges.

INFORMATION in the United States is a formal written accusation of crime prepared and presented to the court by a prosecution official without intervention of the grand jury. Minor offenses may be prosecuted by information in the federal courts, as may infamous crimes not punishable by death when the accused waives his constitutional right to trial on indictment. Informations are employed in prosecutions for all serious crimes in some states of the U.S., but in others their use is limited by state constitutional provisions. Under certain circumstances informations are used in English criminal cases and in civil proceedings. *See* Criminal Law: *Criminal Procedure.* (F. A. A.)

INFORMATION AGENCY, THE UNITED STATES, was created on Aug. 1, 1953, to conduct the overseas information program of the U.S. government. Foreign information activities formerly conducted by the International Information administration and the Technical Cooperation administration of the department of state and by the Mutual Security agency were consolidated in the new agency. The foreign information program was established to promote support among other peoples for the foreign policies of the United States. Field operations of the agency were carried out by the U.S. Information service, which established posts throughout the world. The posts, under the general direction of the U.S. chief of mission in each country, were staffed by public affairs officers and specialists in news, radio, film, library and other cultural activities.

The agency provided field posts with various services: the "Voice of America", which broadcast on a world-wide network in many languages and serviced field needs for recorded film and television programs for use by local stations; the press service, which provided news and prints; the motion-picture service, which prepared documentary films on the United States in various languages; the information centre service, which supplied materials for library programs and community activities and also was responsible for the translation and distribution of U.S. books overseas. The agency also co-operated with private U.S. organizations and individuals.

INFORMATION THEORY. One of the most prominent features of 20th-century technology is the development and exploitation of new communication mediums. Concurrent with the growth of devices for transmitting and processing information, a unifying theory was developed and became the subject of intensive research.

This theory, known as communication theory, or, in its broader applications, information theory, is concerned with the discovery of mathematical laws governing systems designed to communicate or manipulate information. It sets up quantitative measures of information and of the capacity of various systems to transmit, store and otherwise process information.

Some of the problems treated relate to finding the best methods of utilizing various available communication systems, the best methods of separating signals from noise and the problem of setting upper bounds on what it is possible to do with a given channel. While the central results are chiefly of interest to communication engineers, some of the concepts have been adopted and found useful in such fields as psychology and linguistics.

Information is interpreted in its broadest sense to include the messages occurring in any of the standard communication mediums such as telegraphy, radio or television, the signals involved in electronic computing machines, servomechanism systems and other data-processing devices, and even the signals appearing in the nerve networks of animals and man. The signals or messages need not be meaningful in any ordinary sense. This theory, then, is quite different from classical communication engineering theory, which deals with the devices employed but not with that which is communicated.

Central Problems of Communication Theory.—The type of communication system that has been most extensively investigated is shown in fig. 1. It consists of the following:

1. An information source which produces the raw information or "message" to be transmitted.
2. A transmitter which transforms or encodes this information into a form suitable for the channel. This transformed message is called the signal.
3. The channel on which the encoded information or signal is transmitted to the receiving point. During transmission the signal may be changed or distorted. In radio, for example, there often is static, and in television transmission so-called "snow." These disturbing effects are known generally as noise, and are indicated schematically in fig. 1 by the noise source.
4. The receiver, which decodes or translates the received signal back into the original message or an approximation of it.
5. The destination or intended recipient of the information.

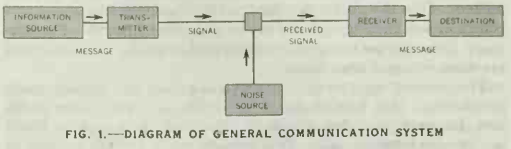

FIG. 1.—DIAGRAM OF GENERAL COMMUNICATION SYSTEM

It will be seen that this system is sufficiently general to include a wide variety of communication problems if the various elements are suitably interpreted. In radio, for example, the information source may be a person speaking into a microphone. The message is then the sound that he produces, and the transmitter is the microphone and associated electronic equipment which changes this sound into an electromagnetic wave, the signal. The channel is the space between the transmitting and receiving antennas, and any static or noise disturbing the signal corresponds to the noise source in the schematic diagram. The home radio is the receiver in this system and its sound output the recovered message. The destination is a person listening to the message.

A basic idea in communication theory is that information can be treated very much like a physical quantity such as mass or energy. A homely analogy may be drawn between the system in fig. 1 and a transportation system; for example, we can imagine an information source to be like a lumber mill producing lumber at a certain point. The channel in fig. 1 might correspond to a conveyor system for transporting the lumber to a second point. In such a situation there are two important quantities: the rate R (in cubic feet per second) at which lumber is produced at the mill, and the capacity C (in cubic feet per second) of the conveyor. These two quantities determine whether or not the conveyor system will be adequate for the lumber mill. If the rate of production R is greater than the conveyor capacity C, it will certainly be impossible to transport the full output of the mill; there will not be sufficient space available. If R is less than or equal to C, it may or may not be possible, depending on whether the lumber can be packed efficiently in the conveyor. Suppose, however, that we allow ourselves a sawmill at the source. This corresponds in our analogy to the encoder or transmitter. Then the lumber can be cut up into small pieces in such a way as to fill out the available capacity of the conveyor with 100% efficiency. Naturally in this case we should provide a carpenter shop at the receiving point to fasten the pieces back together in their original form before passing them on to the consumer.

If this analogy is sound, we should be able to set up a measure R in suitable units telling the rate at which information is produced by a given information source, and a second measure C which determines the capacity of a channel for transmitting information. Furthermore, the analogy would suggest that by a suitable coding or modulation system, the information can be transmitted over the channel if and only if the rate of production R is not greater than the capacity C. A key result of information theory is that it is indeed possible to set up measures R and C having this property.

Measurement of Information.—Before we can consider how information is to be measured it is necessary to clarify the precise meaning of "information" from the point of view of the communication engineer. Often the messages to be transmitted have meaning: they describe or relate to real or conceivable events. However, this is not always the case. In transmitting music, the meaning, if any, is much more subtle than in the case of a verbal message. In some situations the engineer is faced with transmitting a totally meaningless sequence of numbers or letters. In any

case, meaning is quite irrelevant to the problem of transmitting the information. It is as difficult to transmit a series of nonsense syllables as it is to transmit straight English text (more so, in fact). The significant aspect of information from the transmission standpoint is the fact that one particular message is chosen from a set of possible messages. What must be transmitted is a specification of the particular message which was chosen by the information source. The original message can be reconstructed at the receiving point only if such an unambiguous specification is transmitted. Thus in information theory, information is thought of as a choice of one message from a set of possible messages. Furthermore, these choices occur with certain probabilities; some messages are more frequent than others.

The simplest type of choice is a choice from two equally likely possibilities; that is, each has a probability $\frac{1}{2}$. This is the situation, for example, when a coin is tossed which is equally likely to come up heads or tails. It is convenient to use the amount of information produced by such a choice as the basic unit and this basic unit is called a binary digit or, more briefly, a "bit." The choice involved with one bit of information can be indicated schematically as in fig. 2(A). At point b either the upper or lower

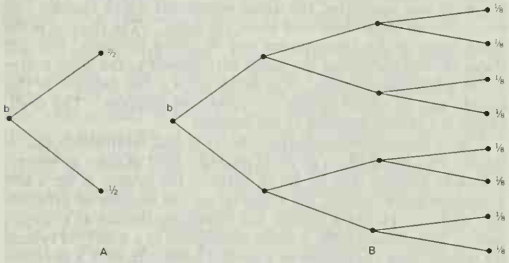

FIG. 2.—A CHOICE FROM (A) TWO POSSIBILITIES; (B) EIGHT POSSIBILITIES (*see* TEXT)

line may be chosen with probability $\frac{1}{2}$ for each possibility.

If there are N possibilities, all equally likely, the amount of information is given by $\log_2 N$. The reason for this can be seen from fig. 2(B), where there are eight possibilities each with probability $\frac{1}{8}$. The choice can be imagined to occur in three stages, each involving one bit. The first bit corresponds to a choice of either the first four or the second four of the eight possibilities, the second bit corresponds to the first or second pair of the four chosen, and the final bit determines the first or second member of the pair. It will be seen that the number of bits required is $\log_2 N$, in this case $\log_2 8 = 3$.

If the probabilities are not equal, the formula is more complicated. When the choices have probabilities $p_1, p_2, \ldots, p_n$, the amount of information H is given by:

$$H = -(p_1 \log_2 p_1 + p_2 \log_2 p_2 + \ldots + p_n \log_2 p_n)$$

This formula for amount of information gives values ranging from zero—when one of the two events is certain to occur (*i.e.*, has a probability of 1) and all others are certain not to occur (probability 0)—to a maximum value of $\log_2 N$ when all events are equally probable (probability $1/N$). These situations correspond intuitively to the minimum information produced by a particular event (when it is already certain what will occur) and the greatest information or the greatest prior uncertainty of the event.

The parlor game "Twenty Questions" illustrates some of these ideas. In this game, one person thinks of an object and the other players attempt to determine what it is by asking not more than 20 questions that can be answered "yes" or "no." According to information theory each question can, by its answer, yield anywhere from no information to $\log_2 2$ or one bit of information, depending upon whether the probabilities of "yes" and "no" answers are very unequal or approximately equal. To obtain the greatest amount of information, the players should ask questions that subdivide the set of possible objects, as nearly as possible, into two equally likely groups. For example, if they have established by previous questions that the object is a town in the United States, a good question would be, "Is it east of the Mississippi?" This divides the possible towns into two roughly equal sets. The next question then might be, "Is it north of the Mason-Dixon line?" If it were possible to choose questions which always had the effect of subdividing into two equal groups, it would be possible to isolate, in 20 questions, one object from approximately 1,000,000 possibilities. This corresponds to 20 bits.

The formula for the amount of information is identical in form with equations representing entropy in statistical mechanics, and suggests that there may be deep-lying connections between thermodynamics and information theory. Some scientists believe that a proper statement of the second law of thermodynamics requires a term relating to information. These connections with physics, however, do not have to be considered in the engineering and other applications of information theory.

Most information sources produce a message which consists not of a single choice but of a sequence of choices; for example, the letters of printed text or the elementary words or sounds of speech. The writing of English sentences can be thought of as a process of choice: choosing a first word from possible first words with various probabilities; then choosing a second, with probabilities depending on the first; and so on. This kind of statistical process is called a stochastic process, and information sources are thought of, in information theory, as stochastic processes. A more general formula for H can be given which determines the rate at which information is produced by a stochastic process or an information source.

Printed English is a type of information source that has been studied considerably. By playing a kind of "Twenty Questions" game, suitably modified, with subjects trying to guess the next letter in an English sentence, it can be shown that the information rate of written English is not more than about one bit per letter. This is a result of the very unequal frequencies of occurrence of different letters (for example, E is very common in English while Z, Q and X are very infrequent), of pairs of letters (TH is very common and QZ very rare), and the existence of frequently recurring words, phrases and so on. This body of statistical data relating to a language is called the statistical structure of the language. If all 26 letters and the space in English had equal frequencies of occurrence (*i.e.*, each had probability $\frac{1}{27}$) and the occurrence of each letter of text was independent of previous letters, the information rate would be $\log_2 27$, or about 4.76 bits per letter. Since only one bit actually is produced, English is said to be about 80% redundant.

The redundancy of English is also exhibited by the fact that a great many letters can be deleted from a sentence without making it impossible for a reader to fill the gaps and determine the original meaning. For example, in the following sentence the vowels have been deleted:

MST PPL HV LTTL DFFCLTY N RDNG THS SNTNC.

As might easily be deduced, redundancy in a language plays an important role in the science of cryptography.

Encoding Information.—An important feature of the measure of information, H, is that it determines the saving in transmission time that is possible, by proper encoding, due to the statistics of the message source. To illustrate this, consider a model language in which there are only four letters—A, B, C and D. Suppose these letters have the probabilities $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$ and $\frac{1}{8}$. In a long text in this language, A will occur one-half the time, B one-quarter of the time, and C and D each one-eighth of the time. Suppose this language is to be encoded into binary digits, 0 or 1, as for example in a pulse system with two types of pulse. The most direct code is the following:

A = 00; B = 01; C = 10; D = 11

This code requires two binary digits per letter of message. By proper use of the statistics, a better code can be constructed as follows:

A = 0; B = 10; C = 110; D = 111

It is readily verified that the original message can be recovered from its encoded form. Furthermore, the number of binary digits used is smaller on the average. It will be, in fact,

$$\tfrac{1}{2}(1) + \tfrac{1}{4}(2) + \tfrac{1}{8}(3) + \tfrac{1}{8}(3) = 1\tfrac{3}{4}$$

where the first term is due to the letter A, which occurs half the time and is one binary digit long, and similarly for the others. It may be found by a simple calculation that $1\frac{3}{4}$ is just the value of H, calculated for the probabilities $\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{8}$.

The result verified for this special case holds generally—if the information rate of the message is H bits per letter, it is possible to encode it into binary digits using, on the average, only H binary digits per letter of text. There is no method of encoding which uses less than this amount.

This important result in information theory gives a direct meaning to the quantity H which measures the information rate for a source or a language. It says, in fact, that H can be interpreted as the equivalent number of binary digits when the language or source is encoded in 0 and 1 in the most efficient way. For instance, if the estimate of one bit per letter, mentioned above as the rate for printed English, is correct, then it is possible to encode printed English into binary digits using, on the average, one for each letter of text; and, furthermore, no encoding method would average less than this.

Capacity of a Channel.—Now consider the problem of defining the capacity C of a channel for transmitting information. Since the rate of production for an information source has been measured in bits per second, we would naturally like to measure C in the same units. The question then becomes, what is the maximum number of binary digits per second that can be transmitted over a given channel? In some cases the answer is simple. With a teletype channel there are 32 possible symbols. By calculating $\log_2 32$ it is found that each symbol represents 5 bits, provided the possible symbols are used with equal probability. Therefore, if we can send n symbols per second, and the noise level is not high enough to introduce any errors during transmission, we can send $5n$ bits per second.

The problem of calculating the capacity of a channel is usually more complex than this example because of disturbing noise. As an example, suppose there are two possible kinds of pulse that can be transmitted in a system, a 0 pulse and a 1 pulse. Suppose further that when 0 is transmitted it is received as 0 nine-tenths of the time, but one-tenth of the time noise causes it to be received as 1. Conversely, suppose a transmitted 1 is received as 1 nine-tenths of the time but distorted into a 0 pulse one-tenth of the time. This type of channel is called a binary symmetric channel. It and other noisy channels have definite capacities that can be calculated by appropriate formulas. In this particular case, the capacity is about 0.53 bits per pulse.

The meaning of the capacity of such a noisy channel may be roughly described as follows: It is possible to construct codes that will transmit a series of binary digits at a rate equal to the capacity. This can be done in such a way that they can be decoded at the receiving point with a very small probability of error. These codes are called error-correcting codes, and are so constructed that the type of transmission errors likely to occur in the channel can be corrected at the receiving point. Finally, it is not possible to transmit at a higher rate than the channel capacity and retain this error-correcting property.

The functioning of error-correcting codes can be likened to the ability of a person to correct a reasonable number of typographical errors in a manuscript because of his knowledge of the structure and context of the language. Much of the work in information theory centres around the theory and construction of such error-correcting codes.

Band-limited Channels.—A frequently occurring restriction on communication channels is that the signals must lie within a certain band of frequencies W cycles per second wide. A result known as the sampling theorem states that a signal of this type can be specified by giving its values at a series of equally spaced sampling points $1/2W$ seconds apart. Thus it may be said that such a function has $2W$ degrees of freedom, or dimensions, per second.

If there were no noise whatever on such a channel it would be possible to distinguish an infinite number of different amplitude levels for each sample. Consequently, in principle, an infinite number of binary digits per second could be transmitted, and the capacity C would be infinite. In practice, there is always some noise, but even so if no limitations are placed on the transmitter power P, the capacity will be infinite, since at each sample point an unlimited number of different amplitude levels may be distinguished. Only when noise is present and the transmitter power is limited in some way does the capacity C become finite. This capacity depends on the statistical structure of the noise as well as the nature of the power limitation.

The simplest type of noise is resistance noise, produced in an electrical resistor by thermal effects. This type of noise is completely specified by giving its average power N.

The simplest limitation on transmitter power is the assumption that the average power delivered by the transmitter is not greater than P. If a channel is defined by these three parameters W, P and N, the capacity C can be shown to be

$$C = W\log_2 \frac{P+N}{N} \text{ (bits per second)}$$

The implication of this formula is that it is possible, by properly choosing the signal functions, to transmit $W\log_2 \frac{P+N}{N}$ binary digits per second and to recover them at the receiving point *with as small a frequency of errors as desired*. It is not possible to transmit binary digits at any higher rate with an arbitrarily small frequency of errors.

Encoding systems in current use, pulse-code modulation and pulse-position modulation, use about four times the power predicted by the ideal formula. Unfortunately, as one attempts to approach more closely this ideal, the transmitter and receiver required become more complicated and the delays increase.

The relation

$$C = W\log(1 + \frac{P}{N})$$

can be regarded as an exchange relation between the bandwidth W and the signal-to-noise ratio P/N. Keeping the channel capacity fixed, the bandwidth can be decreased provided the signal-to-noise ratio is sufficiently increased. Conversely an increase in bandwidth allows a lower signal-to-noise ratio in the channel.

One method of exchanging bandwidth for signal-to-noise ratio is shown in fig. 3. The upper curve represents a signal function whose

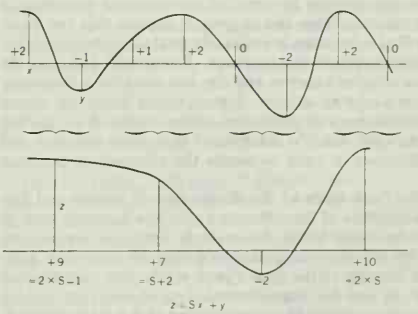

FIG. 3.—THE EXCHANGE OF BANDWIDTH FOR SIGNAL-TO-NOISE RATIO

bandwidth is such that it can be specified by giving the samples shown. Each sample has five amplitude levels. The lower curve is obtained by combining pairs of samples from the first curve as shown. If the pair of samples from the upper curve have amplitudes x and y, a single amplitude z for the lower curve is computed from the formula

$$z = 5x + y.$$

The five possible values of x combined with the five possible values of y produce 25 possible values of z which must be distin-

guished. However, the samples now occur only half as frequently; consequently the band is reduced by half, at the cost of increasing the signal-to-noise ratio. Operating this in reverse doubles the band but reduces the required signal-to-noise ratio.

To summarize, there are three essentially different ways in which bandwidth can be reduced in a system such as television or speech transmission. The first is the straightforward exchange of bandwidth for signal-to-noise ratio just discussed. The second method is utilization of the statistical correlations existing in the message. This capitalizes on particular properties of the information source feeding the channel. Finally, particular properties of the ultimate destination of the messages can be used. Thus in speech transmission the ear is relatively insensitive to phase distortion. Consequently, phase information is not as important as amplitude information, and need not be sent so accurately, resulting in a saving of bandwidth or of power. In general, the exploitation of particular "sensitivities" or "blindness" in the destination requires a proper matching of the channel to the destination.

Filtering and Prediction Problem.—Another type of problem that has been studied extensively in the field of information theory is that of determining the best devices for eliminating noise from a signal and predicting the future value of the signal. These are known as the filtering and prediction problems. The two problems may also occur in combination if it is desired to predict the future value of a noisy signal. Possible applications of the filtering problem occur in the detection of various types of communication signals which have been corrupted by noise or in the smoothing of data subject to observational error. The prediction problem, with or without filtering, may arise, for example, in weather or economic forecasting or in the control of gun directors, where it is desired to predict the future position of a moving target.

The most successful work in this general field has been carried out under the following two assumptions. First, the best prediction or filtering is interpreted to be that which minimizes the mean-square error between the computed value and the true value. Second, the devices performing these operations are assumed to perform linear operations on the signals which they filter or predict. Under these conditions, substantially complete solutions have been found specifying the characteristics of the predicting or filtering device in terms of the power spectra of the signal and of the noise.

Cryptography, Linguistics and Other Applications.—Some applications have been made in the fields of cryptography and linguistics. It is possible to formulate a theory of cryptography or secrecy systems in terms of the concepts occurring in information theory. When this is done, it appears that the information rate R of a language is intimately related to the possibility of solving cryptograms in that language. The smaller this rate, the easier such a solution becomes and the less material is necessary to render such a solution unique. Indeed, within limits, the theory becomes quantitative and predictive, giving means of calculating how much material must be intercepted in a given language and with a given cipher in order to ensure the existence of a unique solution.

A study has been made of the distribution of lengths and frequency of occurrence of the different words in a language such as English. It has been found, for example, that the relative frequency of the nth most frequent word may be expressed quite closely by a formula of the type $P(n + m)^{-b}$, with suitable constants for P, m and b. Experimental data of this type can be explained as consequences of the assumption that a language gradually evolves under continued use into an efficient communication code. (*See* CRYPTOLOGY; LINGUISTICS.)

Psychologists have discovered interesting relationships between the amount of information in a stimulus and reaction time to the stimulus. For example, an experiment can be set up in which there are four lights and four associated push buttons. The lights go on in a random order and the subject is required to press the corresponding button as quickly as possible after a light goes on. It develops that the average time required for this reaction increases linearly with an increase in the amount of information conveyed by the lights. This experimental result holds true under a wide variety of changes in the experiment: the number of lights, the probabilities of different lights, and even varying correlations between successive lights.

These results suggest that under certain conditions the human being, in manipulating information, may adopt codes and methods akin to those used in information theory.

INFORMER, a term variously used to mean (1) a person who, usually in secret, gives information to law-enforcement authorities about an offense, committed by somebody else, which does not necessarily involve injury or loss to the informer himself; (2) an accomplice in crime who earns immunity from prosecution by turning "state's (or queen's) evidence" (*see* EVIDENCE: *Privilege and Public Policy*); and (3) the party who openly initiates criminal proceedings by "laying (or swearing) an information" before a magistrate or sheriff. In England, the status of the so-called "common informer," who was rewarded by the whole or by part of the fine imposed on the offender whom he denounced, was abolished in 1951, and the fines for offenses thus disclosed (*e.g.,* on gaming houses, for breaches of Sunday observance, etc.) are now by statute payable to public funds. Accordingly, both in the U.S. and in Great Britain the word "informer" in its commonest usage means a person, more often than not with a criminal past which he is now capitalizing, who denounces offenders to the police or to other law-enforcement agencies, for payment either *ad hoc* or by retaining fee. (C. H. R.)

INGASSANA, the Arab name for the Negro people of the Tabi hills in Darfur province (eastern Sudan), who have no common name but call themselves JokTau (people of Tau), Jok-Kuthulok, JokGor, etc., after the hills they live upon. Estimated to number about 8,000 in the 1960s, they are horticultural and keep some livestock including cattle, pigs and horses. Each hill is under a religious and political leader, and there is a multiplicity of secular officials. The Ingassana have a sun cult and a sacred stone called *soba* or *mit i tel* (stone of the sun).

See E. E. Evans-Pritchard quoted in C. G. and B. Z. Seligman, *Pagan Tribes of the Nilotic Sudan* (1932); Ernesta Cerulli, "Peoples of Southwest Ethiopia and its Borderlands," *Ethnographic Survey of Africa* (1956). (G. W. B. H.)

INGE, WILLIAM RALPH (1860–1954), English theologian and dean of St. Paul's, was born June 6, 1860, at Crayke, Yorks., the son of William Inge, sometime provost of Worcester college, Oxford, and was educated at Eton, and at King's college, Cambridge. From 1884 to 1888 he was an assistant master at Eton, and during the last two years of that time was fellow of King's college, Cambridge. From 1889 to 1904 he was fellow of Hertford college, Oxford. In 1907 he was made Lady Margaret professor of divinity at Cambridge, and in 1911 he became dean of St. Paul's. His sermons attracted attention because of their criticism of modern life and their pessimistic tone, which earned him the sobriquet "the gloomy dean." Inge died Feb. 26, 1954, at Wallingford, Eng.

Among Inge's numerous theological and devotional works may be mentioned *Christian Mysticism* (Bampton lectures; 1899); *Types of Christian Saintliness* (1915); *Philosophy of Plotinus* (Gifford lectures; 2 vol., 1918); *Outspoken Essays* (1919, 2nd series 1922); *Personal Religion and the Life of Devotion* (1924); *The Platonic Tradition in English Religious Thought* (Hulsean lecture; 1926); and *Christian Ethics and Modern Problems* (1930).

INGEBORG (*c.* 1176–1237 or 1238), queen of France, was the sister of Canute VI. king of Denmark. She married in 1193 Philip II Augustus, king of France, but on the day after his marriage the king took a sudden aversion to her. The French council of Compiègne acceded to his demand for a declaration of nullity, but popes Celestine III and Innocent III successively took up

Ingeborg's defense. Philip, having married Agnes of Meran in June 1196, was excommunicated; and, as he remained obdurate, France was placed under an interdict. Agnes was finally put aside, but Ingeborg was held in the château of Étampes until, in 1213, Philip, hoping perhaps to justify by her claims his pretensions to England, acknowledged her again as queen of France. She survived him more than 14 years, respected by all.

See R. Davidssohn, *Philipp II August von Frankreich und Ingeborg* (1888); E. Michael, "Zur Geschichte der Königin Ingeborg," *Zeitschrift für Katholische Theologie* (1890).

INGELOW, JEAN (1820–1897), English poet and novelist, popular in her own day, and now remembered for one narrative poem, "High Tide on the Coast of Lincolnshire, 1571," which exemplifies her command of language, skill in handling metre, and power to evoke feeling. Born at Boston, Lincolnshire, on March 17, 1820, and educated in a cultured family circle, she moved to London in 1863 and spent the rest of her life there, dying in Kensington on July 20, 1897. Modest and retiring, she used much of the income from her writings in charitable works and, though acquainted with Tennyson, who greatly admired her work, Browning, the Rossettis and many other painters and writers, took little part in social life. *Poems* (1863) contains her best work. It also brought her fame, 23 editions being published by 1880. A second series appeared in 1874, and a third in 1885. *Sarah de Berenger* (1879) is perhaps her best novel, and her excellent books for children include *Mopsa the Fairy* (1869; reprinted, 1964).

INGEMANN, BERNHARD SEVERIN (1789–1862), Danish poet and novelist, whose works glorifying his country in the middle ages remained popular reading in Denmark for several generations, was born at Torkildstrup, Falster, on May 28, 1789. He was educated at Slagelse grammar school and admitted to Copenhagen university in 1806. His early poetry was influenced by German romanticism, and much of it is sickly and sentimental. His first volume of poems (1811) and his verse tale, *Varners poetiske Vandringer* (1813), had a certain popularity in the romantic age but are hardly readable today. His verse romance, *De Sorte Riddere* (1814), and his tragedy, *Blanca* (1815), were well received by the public but strongly attacked by the critics. After his appointment as schoolmaster at Sorø in 1822, he wrote a series of historical novels, of which the first, *Valdemar den Store og hans Mænd* (1824), and the last, *Dronning Margrethe* (1836), were in verse, the other four in prose: *Valdemar Seier* (1826; Eng. trans., *Waldemar, Surnamed Seir*, 1841), *Erik Menveds Barndom* (1828; Eng. trans., *The Childhood of King Erik Menved*, 1846), *Kong Erik og de Fredløse* (1833; Eng. trans., *King Erik and the Outlaws*, 1843) and *Prins Otto af Danmark* (1835). Among his poetic works are the impressive verse cycle *Holger Danske* (1837) and, most significant of all, his many beautiful and simple *Morgen- og Aftensange* (1839), written over a period of years and still very popular in Denmark. One hymn by Ingemann has become well known in English translation, "Through the Night of Doubt and Sorrow." He died at Sorø on Feb. 24, 1862.

Bibliography.—*Samlede Skrifter*, 41 vol. (1845–65); *Historiske Romaner*, 4 vol. (1911–12); *Bernhard Severin Ingemanns Levnetsbog* (1862). *See* also H. (E. L. Bf.)

INGENHOUSZ, JAN (1730–1799), Dutch-English physician and scientific investigator, who discovered the principles underlying photosynthesis. Born in Breda, Holland, on Dec. 8, 1730, he received his medical degree at Louvain in 1752. After advanced studies in Leiden, Paris and Edinburgh, he returned to his native city in 1757 and then about 1765 moved to London, where he achieved prominence by his success with variolation, the use of human virus in inoculation against smallpox. In 1768 he went to Vienna at the invitation of the empress Marie Therese, inoculated her family and became court physician. He returned to London in 1779 and in that same year published a small book entitled *Experiments on Vegetables, Discovering Their Great Power of Purifying the Common Air in Sunshine, but Injuring It in the Shade or at Night*. His work described gaseous interchange between plants and the atmosphere and the influence of light upon this process. He also conducted investigations in electricity, inventing improved apparatus for generating large amounts of static electricity. His other fields of interest included soil nutrition and heat conduction in metals. He was elected to the Royal society in 1779. Ingenhousz died at Bowood on Sept. 7, 1799.

Bibliography.—J. Wiesner, *Jan Ingenhousz, sein Leben und sein Wirken als Naturforscher und Arzt* (1905); H. S. Reed, *Jan Ingenhousz, Plant Physiologist*, "Chronica Botanica," vol. 11 (1950); Leonard K. Nash (ed.), *Plants and the Atmosphere* (1952). (M. C. L.)

INGERMANLAND, or Ingria, is the name formerly given to that part of Russia lying along the southeastern shores of the Gulf of Finland, which Peter the Great conquered from Sweden in 1701–04, between Leningrad and Narva. It is now known as Izhorskaya Zemlya and lies largely within Leningrad *oblast* and parts of Pskov *oblast*. (R. A. F.)

INGERSOLL, ROBERT GREEN (1833–1899), U.S. orator, politician and lawyer, who popularized the higher criticism of the Bible, a humanistic philosophy, and a scientific rationalism which qualified him as the "bull dog" for Charles Darwin in the United States, was born in Dresden, N.Y., Aug. 11, 1833. The self-educated son of a peripatetic Congregational minister, he had little formal education. Admitted to the Illinois bar in 1854, Ingersoll subsequently enjoyed a lucrative law practice in Peoria, Washington, D.C., and New York city. His Civil War service as a colonel of Illinois volunteer cavalry was terminated in 1862 when he was captured and paroled by Confederate General Nathan Bedford Forrest. As an orthodox Republican he was attorney general of Illinois, 1867–69, the "big voice" of the party in the presidential campaigns of 1876 and 1880 (he gave James G. Blaine the soubriquet "The Plumed Knight"), and leading counsel for Republican defendants in the Star Route Scandal of 1882. In spite of his contributions to the party as a speaker, his unorthodox religious views deterred Republican administrations from appointing him to the cabinet or diplomatic posts which he desired. Nationally known as a lecturer, he was in great demand and received as much as $3,500 for a single evening's performance. He died at Dobbs Ferry, N.Y., July 21, 1899. His principal lectures and speeches—which bear such titles as *Some Mistakes of Moses* and *Why I Am An Agnostic*—are found in *The Works of Robert G. Ingersoll*, edited by Clinton P. Farrell, 12 volumes (1902).

See C. H. Cramer, *Royal Bob*, a biography (1952). (C. H. Cr.)

INGERSOLL, ROBERT HAWLEY (1859–1928), U.S. merchant and manufacturer, was born at Delta, Eaton, Mich., Dec. 26, 1859. He spent his youth on his father's farm and had a very limited formal education. At the age of 20 he went to New York city and, with his savings of $1,600, established a business manufacturing and selling rubber stamps. With his two brothers he expanded it to include a wide variety of novelty products including the dollar Ingersoll watch. This became known as "the watch that made the dollar famous," about 70,000,000 being sold by 1919. He lost control of the firm in 1921 but in 1924, in a new venture, successfully introduced a dollar razor strop. Ingersoll died in Denver, Colo., Sept. 4, 1928. (H. J. Sg.)

INGERSOLL, ROYAL EASON (1883–), U.S. naval officer who commanded the Atlantic fleet in World War II, was born in Washington, D.C., June 20, 1883, son of Rear Adm. Royal Rodney Ingersoll. He graduated from the U.S. Naval academy in 1905 and thereafter held a wide range of naval assignments. He became a rear admiral in 1938, a vice-admiral in Jan. 1942 and an admiral in July of that year. As commander in chief of the Atlantic fleet from Jan. 1942 to Nov. 1944 he had the responsibility of conducting antisubmarine warfare, escorting convoys and transporting both troops and supplies to Europe and north Africa. In Nov. 1944 he became deputy commander in chief U.S. fleet and commander of the western sea frontier, in which post he continued until Dec. 1945. He retired on Aug. 1, 1946. (J. B. Hn.)

INGLEWOOD, an industrial and residential city in west-central Los Angeles county, Calif., U.S., a part of the Los Angeles metropolitan area and site of the Los Angeles International airport. Inglewood's industry includes aircraft manufacturing, metal products, pottery production and oil refining. An additional feature is the large race track, Hollywood Park.

The first settlers to enter the area were attracted by the *Aguaje de la Centinela* ("Sentinel Springs"). In 1822 Antonio Avila was given permission by the Mexican government to keep stock around the springs. The Avila family continued to hold the springs area until 1855, when the grant was confirmed by the California state government after a three-year land-claim survey. In 1887 it was acquired by the Centinela-Inglewood Land company, made up of seven Los Angeles real estate investors. Surveyors laid out the townsite during August and September. A railroad connecting Inglewood with Los Angeles was completed the next spring. By that time several small businesses and a hotel were already in operation. Inglewood was incorporated as a California city in 1908 and gained a freeholder charter in 1927. Its greatest proportional growth came between 1920 and 1925. The 1960 census showed a population of 63,390. For comparative population figures *see* table in CALIFORNIA: *Population*. (J. M. Wo.)

INGLIS, CHARLES (1734–1816), first Anglican colonial bishop, was born in Donegal, Ire. In 1754 he emigrated to Pennsylvania where he taught at a school in Lancaster for four years. After ordination in England (1758) he worked at the Dover mission station, Delaware, and from 1765 to 1783 he was assistant, then rector, at Trinity church, New York. He furthered the conversion of the Mohawk Indians and advocated the setting up of an American episcopacy. Because of his fervent loyalty to the crown, his property was confiscated during the American Revolution and he fled in 1783 to Great Britain. In co-operation with the Society for the Propagation of the Gospel he persuaded the British government to pass a statute that permitted the consecration in England of bishops for the new American republic. He himself was consecrated bishop of Nova Scotia in 1787.

Bishop Inglis had oversight of a vast diocese which included for a time not only the Atlantic provinces but also the present Quebec and Ontario. He faithfully performed his ecclesiastical duties and was responsible for building over 20 churches. Through his efforts an academy and a college were founded at Windsor in 1788 and 1789, now known respectively as King's Collegiate school and the University of King's college (later moved to Halifax). In 1808 the bishop was made a member of the executive council of the province. He died at Clermont, near Aylesford, N.S., Feb. 24, 1816.

See J. W. Lydekker, *Life and Letters of Charles Inglis* (1936); R. V. Harris, *Charles Inglis, Missionary, Loyalist, Bishop* (1937).
(T. R. M.)

INGLIS, SIR CHARLES EDWARD (1875–1952), British professor of engineering distinguished as a teacher and for his researches into bridge vibrations, was born at Worcester on July 31, 1875. His early researches concerned mechanical vibrations, but in 1913 he published an important paper on the stresses in a plate due to the presence of cracks. He investigated railway bridge vibration from 1923 to 1934. During World War I he designed an easily transportable bridge, bearing his name, which was adopted by the British army and much used in 1917–18. In 1919 Inglis was appointed professor of mechanical sciences and head of the department of engineering, Cambridge university, in succession to Bertrand Hopkinson. On his retirement in 1943 the department had become one of the most important engineering schools in the world. He died in Suffolk, April 19, 1952. (J. F. Br.)

INGLIS, SIR JOHN EARDLEY WILMOT (1814–1862), British major general, son of John Inglis, third bishop of Nova Scotia, was born at Halifax, Nova Scotia, on Nov. 15, 1814. In 1833 he joined the 32nd foot, in which all his regimental service was passed. He saw active service in Canada during the rebellion of 1837 and in the Punjab (1848–49), being in command at the storming of Multan and at the battle of Gujrat. In 1857, on the outbreak of the Indian mutiny, he was in command of his regiment at Lucknow. Sir Henry Lawrence being mortally wounded during the siege of the residency, Inglis continued the defense for 87 days against an overwhelming force, for which he was made a knight commander of the Bath and promoted to major general. After further service in India, he was given command of the British troops in the Ionian Islands in 1860. He died at Hamburg, Ger., on Sept. 27, 1862. (C. B. Fe.)

INGOLD, CHRISTOPHER KELK (1893–), English organic chemist, born Oct. 28, 1893, at Ilford, was educated at University college, Southampton, and the Imperial College of Science and Technology, London, where he received a doctor of science degree in 1922. After lecturing at the Imperial college, Ingold became professor at Leeds, 1924–1930, University college of London university, 1930–37, and director of the chemical laboratories at University college in 1937. Ingold excelled in studies of resonance, mesomerism, electronic interpretations, clarification of constitution of organic substances and their reactions, developments of steric hindrance and use of deuterium in research. He received many honours and awards, including the royal medal of the Royal society (1952) for investigations of the mechanism and factors affecting organic reactions. He was Baker lecturer at Cornell university, Ithaca, N.Y., in 1950, and published *Structure and Mechanism in Organic Chemistry* (1953), authoritative for stereochemistry and reaction mechanics. (V. Bw.)

INGOLSTADT, a town of Germany, *Land* (state) of Bavaria, which after partition of the nation following World War II became part of the Federal Republic of Germany, is situated on the Danube, 80 km. (50 mi.) N. of Munich by road. Pop. (1961) 53,405. The old town is partly surrounded by the early Gothic (14th-century) town walls with the picturesque Cross gate, and is intersected by four main streets lined with old houses in various styles. The massive Late Gothic brick cathedral of the Virgin (1425) is a landmark, and nearby stand the former university buildings and the late baroque church of Maria de Victoria. In the eastern part of the town is the ducal castle (1417) with fine interior, museum and art collection. A ring of parks separates the town from the surrounding factory and residential districts.

Ingolstadt is a junction where the Regensburg-Ulm and Nürnberg-Munich railways cross. The Nürnberg-Munich *Autobahn* touches the town's eastern boundary. Industry includes the manufacture of automobiles, machinery, textiles and electrical equipment. With the linking of Genoa, Italy, and Marseilles, France, by pipelines and the construction of refineries, Ingoldstadt area has become the Bavarian centre of petroleum refining.

First mentioned in 806 as a crown estate, "villa Ingoldestat," it became a city in the 13th century and in 1392 a ducal seat. In 1447 the duchy of Bavaria-Ingolstadt passed to the Landshut family and later to the Munich line of the Wittelsbachs. The Bavarian university, important in the German humanist movement and the Counter-Reformation, was founded in 1472, but in 1800 was transferred to Landshut and in 1826 to Munich. In the 19th century Ingolstadt was made a garrison and fortress town. After World War II, despite serious damage, industry developed rapidly.
(R. Ko.)

INGRAM, JOHN KELLS (1823–1907), Irish scholar and economist who made a reputation in the fields of literature, philosophy, science and political economy, was born in County Donegal, Ireland, on July 7, 1823, and educated at Newry school and Trinity college, Dublin. Elected fellow of his college in 1846, he became successively professor of oratory and English literature (1852–66), regius professor of Greek (1866–77), and librarian (1879–87). Remarkable for his versatility, he contributed a historical and biographical article on economics to the 9th edition of the *Encyclopædia Britannica* which was translated into many European languages. He died in Dublin on May 1, 1907. His principal works are *Greek and Latin Etymology in England; The Outlines of the History of Religion* (1900); *Human Nature and Morals According to A. Comte* (1901); *Practical Morals* (1904); and *Sonnets and Other Poems* (1900).

INGRAM, JONAS HOWARD (1886–1952), U.S. naval officer who during World War II supervised the convoy of thousands of U.S. troops to the European theatre, was born in Jeffersonville, Ind., Oct. 15, 1886. He entered the U.S. Naval academy in 1903 and graduated in 1907. He became a rear admiral on Jan. 10, 1941, vice-admiral on Feb. 2, 1942, and admiral on Nov. 15, 1944. In 1941 he commanded a cruiser division in the Atlantic, and afterward he became commander 4th fleet and commander South Atlantic force with headquarters in Brazil. He was most successful in his dealings with the South American nations and with Brazilian

naval units serving under his command. His fleet was very efficient in antisubmarine warfare. On Nov. 15, 1944, he became commander in chief U.S. Atlantic fleet, and continued in this post until Sept. 1946. He retired April 1, 1947, and died at San Diego, Calif., Sept. 10, 1952. (J. B. Hn.)

INGRES, JEAN AUGUSTE DOMINIQUE (1780–1867), French painter, the leader of the classical tradition in French 19th-century painting, was born at Montauban in Gascony on Aug. 29, 1780. His father was an impecunious ornamental sculptor, painter and drawing master who encouraged his eldest child from the very early moment that the boy's gifts for drawing and music became apparent. In 1791 Ingres first attended classes at the academy at Toulouse. The personalities of none of his early teachers left their mark, though Ingres' lifelong love of Raphael dates from his boyhood. In Aug. 1797 he went to Paris and entered the atelier of J. L. David, moving two years later to the École des Beaux-Arts. After no more than a few weeks there he won the torso prize; and in 1800 he was equal second in the Prix de Rome, which he won outright the following year with a painting in the style of David's "Sabine Women," "The Envoys From Agamemnon Before Achilles" (École des Beaux-Arts, Paris).

Unsettled political and economic conditions led to the postponement of the award, and Ingres had to wait until the autumn of 1806 before he could leave for Rome. In the meantime he was given important official portrait commissions, and was provided with a studio in the old Capucine convent, now state-owned, where A. Gros, A. L. Girodet and Ingres' student friends François Granet and Lorenzo Bartolini worked. "The Envoys From Agamemnon" was warmly praised by John Flaxman, whose influence may be seen in several of Ingres' early works, among them the sketch "Venus Wounded by Diomedes" (*c.* 1803, Hirsch collection, Basel) and "Jupiter and Thetis" (1811, Aix-en-Provence). Flaxman was at this time famed throughout Europe as a vase painter for Josiah Wedgwood and as an illustrator of Homer, and his friezelike compositions and bold use of unshaded line were regarded as quintessentially classical qualities by Ingres and his friends. They found Flaxman's style more convincing than the new "Greek" manner of their master David. Ingres borrowed freely from Flaxman's illustrations and from contemporary engravings of Greek sculpture and vase designs. He was deliberately building up a repertory of forms that he continued to use in classical compositions throughout his life. Perhaps aware of the poverty of his imagination, Ingres made a virtue out of copying.

MUSÉE DU LOUVRE

"LE BAIN TURC" ("THE TURKISH BATH") BY J. A. D. INGRES, COMPLETED 1863. IN THE LOUVRE

Apart from the classical figure compositions the young Ingres was also painting portraits. Several were shown at the Salon of 1806, where they were met with incomprehension and ridicule. Ingres' portrait style was indeed an unusual one, owing much to Raphael. In self-portraits and portraits of friends, the sitters are strongly individualized and given a mysterious, almost tormented air—the touch of romanticism often found in Ingres. But in commissioned works, like the three Rivière portraits (Louvre, Paris) or Mme. Aymon (Rouen), the artist does not attempt to express the character of his sitters, though their bourgeois origins are plain.

Ingres is not concerned with naturalism of any sort but with the creation of an abstract design in which the forms of the natural world are shaped into an eloquent surface pattern. His remarkable natural feeling for line allows him to describe form by contour alone. In the most revolutionary portraits, like that of Mme. Rivière, an arabesquelike pattern of lines dominates the picture, and Ingres seems to have abolished space, reducing body, clothes and cushions to a single unified plane. Natural forms are given an unreal near-geometrical smoothness, and are then held in perfect equilibrium by the linear pattern of the picture. Colour is always subservient to line, though Ingres has a strong feeling for texture and delights in rendering rich stuffs. These same qualities may be found in the great series of female nudes which begins in 1807 with the Bonnat and Valpinçon "Baigneuses" ("Bathers," Bayonne and Louvre) and reaches its climax in "Le Bain Turc" ("The Turkish Bath," Louvre).

The "Baigneuses" were painted in Rome; Ingres had finally left Paris in 1806 and did not return when his scholarship expired in 1810. He stayed in Rome, earning a living from the portraits and portrait drawings in pencil, now so admired, which to Ingres were a form of drudgery that prevented his working on the large history pieces he wished to paint. Ingres was planning both classical (Homeric) and historical (Raphaelesque) compositions: two distinct manners that persist in his work. The first large Homeric composition, "Jupiter and Thetis," met only with disapproval when sent back to Paris in 1811. Because he disliked all Italian painting after Raphael, Ingres was accused of archaizing tendencies.

In 1814 and 1819 Ingres again sent work to the Paris Salon, including some pictures in the new "troubadour" style—scenes of medieval history depicted in quasi-realistic manner (events in the lives of Henri IV, of Aretino, of Raphael; and a series of great lovers). He was still much criticized. In 1820 he moved from Rome to Florence; his altarpiece, "Christ Giving the Keys to Peter" (Louvre), had won some favour, and he was now at work on another religious picture, "The Vow of Louis XIII," commissioned for Montauban cathedral. Ingres returned to France in 1824 to show this at the Salon. It met with universal approbation, appealing to classicist, romantic and troubadour taste alike. A most ambitious design, it represents the culmination of Ingres' Raphaelesque manner.

After 18 years' absence in Italy, Ingres became a Parisian celebrity overnight. He was given the cross of the Legion of Honour by Charles X, elected to the French Academy, and asked to paint "The Martyrdom of St. Symphorian" for Autun cathedral and "The Apotheosis of Homer" for the ceiling of the new museum in the Louvre. He opened a studio and quickly had more than 100 students. The Louvre picture was completed by 1827. It celebrated an early enthusiasm of Ingres', one that also inspired the "Homer Deified" on which he was working at the time of his death. In the "Apotheosis" Ingres' Raphaelesque and Homeric manners are combined. The second commission, for Autun, gave Ingres much difficulty and when exhibited at the Salon of 1834 it was adversely criticized. Greatly upset, Ingres vowed never to show at the Salon again. He stopped painting for a time and left Paris to become director of the French academy in Rome.

He returned to Paris in 1840 and the last 26 years of his life were comparatively uneventful. The most considerable project was a decorative scheme for the château of Dampierre, which occupied Ingres from 1843 until 1850 when work was abandoned. "The Golden Age," unfinished and ruined as it is, marks the revival of mural painting in France which culminates in the work of T. Chassériau and Puvis de Chavannes.

Ingres also continued to paint portraits, religious pictures, nudes and figure compositions, of which "Le Bain Turc" (Louvre), completed 1863, is the most important. Into it he introduced, almost without change, the figure of the "Valpinçon Baigneuse" which he had painted in 1808. Ingres was never against imitation or copying, and replicas by his own hand abound. In 1846 and 1855 retrospective exhibitions of his works were arranged. Ingres died in Paris on Jan. 14, 1867.

Charles Baudelaire, although as the champion of Eugène Delacroix he cannot be regarded as unbiased, laid the foundations of later estimations of Ingres. He perceived that Ingres was a draftsman of genius, who, seeing colour as no more than an inessential prettifying ornament, ruthlessly subordinates it to line. He noticed Ingres' lack of creative imagination, and the way in which he develops little, but switches from style to style. The entire production of Ingres' long output is implicit in the impressionable early years, and, as Baudelaire says, *comme il n'a pas progressé, il ne vieillera pas* ("because he has not progressed, he will not age").

Though affected by romanticism, the David-trained Ingres was a classical artist. His classicism made him abstract from the natural world for the sake of pictorial composition. This and his powers of draftsmanship help to explain why he has never lacked admirers, and why Degas, Gauguin, Matisse and Picasso were all profoundly influenced by his work. Many of Ingres' major works are now in the Louvre museum; he bequeathed the contents of his studio, including 4,000 drawings and 30 paintings, to his native town of Montauban.

INGRESS, entrance as opposed to exit or egress; in astronomy, the apparent entrance of a smaller body upon the disk of a larger one, as it passes between the latter and the observer; in this sense it is applied especially to the beginning of a transit of a satellite of Jupiter over the disk of the planet.

INGUSHETIA: *see* Chechen-Ingush Autonomous Soviet Socialist Republic.

INHERITANCE. This article deals with the anthropological and historical background of the inheritance of property and with the policies by which its regulation is determined. The basic features of the Anglo-American law of inheritance are presented in the articles Intestate Succession; Will; Estates, Administration of; Probate; Estate and Inheritance Taxes.

In its broadest sense inheritance or heritage means transfer of something from earlier to later ages or generations. We thus speak of an individual's inherited traits of body or character and of the cultural heritage of one civilization from another. In a more specific sense inheritance signifies the devolution of property upon the death of its owner intestate. In modern society this devolution is regulated in minute detail by law. In continental Europe the pertinent branch of law is generally called the law of succession. In England until 1926 it was usual to distinguish between descent of real estate and distribution of personal estate. The rules applicable to the two kinds of property have since been greatly assimilated to each other, but no common term has as yet come to be universally accepted. In England books dealing with the subject are frequently entitled "On Executors and Administrators." In the United States the term probate law is frequently, although inaccurately, applied to the field as a whole. Following the title of an important statute of the state of New York, the term "law of decedents' estates" has been gaining ground, and occasionally one finds the term "law of succession upon death." The word inheritance is used as the technical term of Scots law. The title of the present article has been chosen in accord with the usage of anthropologists and other social scientists.

Inheritance and Individual Ownership of Property.—Inheritance of property cannot occur unless goods are regarded as belonging to individuals rather than groups and unless such goods are of such permanence that they continue to exist and to be useful beyond the death of the owner. Among primitive food gatherers and hunters it has not been uncommon for such personal belongings as weapons or bowls to be destroyed after the death of the owner in order to protect the survivors from being molested by his spirit. Among the Papua of New Guinea or the Bergdama (Mountain Damara) of south Africa the hut of the dead man was abandoned or burned down so as to ban the magic of the disease of which the owner died. Among the Herero of southwest Africa the dead man's goats were slaughtered and eaten; this seems to have been connected with the fear that they were affected by his magic, but also with the belief that the spirits of the slaughtered goats would follow the dead owner into the realm of spirits where he would need them. This belief in providing for the needs of the dead seems to have been the root of the widespread custom of burning or burying with the body victuals, utensils, treasure, slaves or wives. Tombs have yielded rich evidence of such practices in the cultures not only of North American Indians or European Stone and Bronze Age man but also of the high civilizations of ancient Egypt or pre-Columbian Mexico. Another way of disposing of a dead man's effects in primitive society was to distribute them among more remote relatives and friends, as has occurred among Indian tribes such as the Delaware and the Iroquois. Distribution of this sort, in the absence of rules of inheritance, could easily lead to quarrel and violence, as was evidently the case among the Comanche.

The view of the classical writers of Marxian socialism that common ownership of all goods, or at least of land, once constituted a universal stage of mankind, can be neither proved nor disproved. While the absence of individual ownership of land among nomadic food gatherers, hunters and herders should not be regarded as group ownership of the land over which the group roams, group ownership has been widespread, but by no means universal, among primitive and archaic agriculturalists. It has, indeed, persisted into modern times in India and parts of Africa and Asia, and it played a considerable role in the development of the Teutonic and Slavic peoples of Europe. In parts of Yugoslavia ownership of the land by zadruga, *i.e.*, large groups of progeny of a common ancestor, has continued into the 20th century. In western Europe the common ownership of pastures and woods, which grew out of the former system of common ownership of the land of a village, can still be found, especially in the Alpine regions of Switzerland and Austria. The impact of modern mechanization and industrialization upon the village community can currently be observed in India. While in earlier times colonization of new land tended to be carried on by groups, for instance, the German settlement of the regions east of the Elbe in the 10th to 13th centuries, the settlement of Europeans in North America, Australia, Africa and other parts of the world took place in accord with the economic ideals of the classical economists of the 18th and 19th centuries, who regarded individual ownership of land as the type most favorable to efficient land use. Socialist ideas combined with large-scale mechanization have resulted in new forms of land ownership in common: the *kolkhozy* of the Soviet Union, the communes of Communist China, or the *kibbutzim* of Israel. Wherever land is held in common, the death of a member of the group results not in inheritance but in a rearrangement of duties, and of rights of participation in the produce or rights of temporary usage of the land itself. (*See* also Communism, Primitive; Land Tenure, Primitive.)

Critiques of Inheritance.—The institution of inheritance has been attacked because it renders possible the acquisition of wealth without work, and because it is regarded as a principal source of inequality of income. Such attacks have come not only from certain extremists to whom complete equality of income appeals as a social ideal, but also from more thoughtful observers to whom great differences in the distribution of wealth appear to be incompatible with modern views of the dignity of man. Against such attacks inheritance has been defended on economic as well as on moral grounds.

Most of the attacks appear to be directed against the institution of private property as such rather than merely against its transfer upon death (*see* Socialism). Within the framework of an economy of individual property, inheritance has been said to be necessary to guarantee the continuity of enterprise, without which long-range economic activity could not flourish. The argument has lost much of its force in an economic system in which large-scale enterprise has come to be carried on in corporate form, and thus to be directed not by owners but by specialists in management succeeding each other in the manner of officeholders. For the same reason there is also less force in the argument that without the incentive of handing on the fruits of one's work, competition, and consequently the growth of the total economy, would be hampered.

Theoretically, it is possible to conceive of a social system in which a person's property rights would end with his death. If the assets left behind were not reassigned to some other individual, the eventual result would be complete ownership of all wealth by the community, and the system of individual property would end. A new individual owner could be determined in one of four ways: reassignment to the first taker, a practice that would produce strife and disorder; reassignment by a governmental agency, which would constitute an exercise of power regarded as incompatible with a free society; reallotment in accordance with set-

tled rules generally fixed for all; or reallotment in accordance with the wishes of the decedent. The last two are exactly the ways in which the modern western systems of inheritance work: the estate is realloted according to the rules of intestacy law or according to the will of the decedent.

The only debatable issues within a system of private ownership are: who are to be the takers in intestate succession and whether or not and, if so, within what limits, freedom of testation shall be permitted. In all societies inheritance has developed as an incident of kinship. Even in a society in which ownership of property is regarded as belonging to individuals rather than kinship groups, the feeling of belonging to one's group is still so strong, especially between parents and children, that a man's sense of freedom from governmental power would not be complete unless he knew that he could pass on his possessions to his children. There arises, however, the question of whether inheritance shall extend beyond the circle of those persons with whom the decedent was connected by ties of affection or about whose well-being he was, or should have been, concerned. In the urbanized and migratory population of highly industrialized nations, the family as a felt unit has tended to shrink to the small circle of husband, wife and children. Ties of relationship tend to be weak even among first cousins. Shall the estate of a person dying intestate without close relatives pass to some distantly related "laughing heir"? In an age of expanding demands on government, there has been an inclination to prefer the needs of the public treasury over allotment to a distant relative based upon no ground other than the necessity of finding an individual heir. A further argument for limiting intestate succession to the circle of close relationship is based on the difficulty of tracing remote heirs, the fractionalization of estates that easily occurs in such cases and the temptation to litigation. In England, the circle of intestate takers has thus been limited by the Administration of Estates act, 1925, to descendants of the same grandparents as the deceased. More limiting are the intestacy laws of the Soviet and the Peoples' republics. Under the law of the U.S.S.R., which constitutes the general model of these laws, intestate succession is limited to descendants, the surviving spouse, non-able-bodied parents and other persons who were actually dependent upon the decedent for the year prior to his death.

Another way of limiting the rights of remote relatives for the benefit of the public treasury consists in increasing the rates of inheritance taxes in proportion to the remoteness of the relationship between the takers and the decedent. In the United States the federal tax on succession depends solely on the size of the estate, whereas the additional inheritance taxes levied by the states are widely patterned upon such a scale. This can also be found in numerous other countries, but not in England since 1949.

Inheritance taxation is also used to reduce that effect of inheritance for which it has been most consistently blamed: namely, its tendency to increase the inequalities in the distribution of wealth. This effect has, it is true, been praised as a virtue by conservative advocates of a class society who were impressed with the creation and preservation of cultural values that only an aristocracy seems to be able to develop. Those claims for unpartitioned inheritance by one heir which found expression in the English tradition of primogeniture were aimed at the exact opposite of what societies more interested in equality seek to achieve by compulsory partition, as under French or German law, or by means of progressive inheritance taxation, as in the United Kingdom or the United States, or by a combination of both. The law of inheritance and inheritance taxation thus constitute an effective means of social policy.

The critique of inheritance as such based upon the ground that it tends to increase inequalities of wealth has lost much of its significance not only because it has been found possible to counteract that effect by the means mentioned but also by the general development of modern society, which may have well been helped by these measures. In contrast to the conservative class society of 19th-century Europe, new countries like the United States presented opportunities not only for the active to acquire wealth on his own but also to the less capable of quickly losing what he might have inherited. Above all, the spread of general education has tended to diminish the advantage which the child of the wealthy would have over that of the poor, and the general suffrage, partly a result of these developments, has further tended to broaden the sphere of sharing the wealth.

An impressive illustration of the connection between a society's basic policies and the shape of its law of inheritance is constituted by inheritance legislation in the Soviet Union. In the early stage of the Bolshevik revolution, inheritance was limited to the descent of a moderate amount of property to close relatives or to the surviving spouse, provided they were in need. The limit upon the size of the property, 10,000 gold rubles, roughly equal to $5,500, was lifted in 1926, and the requirement of need was abolished for inheritance by the surviving spouse, descendants, parents, brothers and sisters. If there are no intestate heirs, the estate may (since 1945) be freely disposed of by will. Since private property cannot exist in means of production, inheritance, too, is limited to goods of use or consumption and to individual savings invested in government bonds or saving accounts. Within the limits stated, inheritance and freedom of testation are regarded as constituting useful incentives to creative productiveness without constituting a danger to the socialist system. Inheritance in those objects in which private property is permitted is thus listed in the constitution of 1926 as one of the rights in the enjoyment of which the citizens are protected by the law (art. 10).

Divided or Undivided Inheritance (Primogeniture).— The problem whether, and to what extent, freedom of testation should be permitted is discussed in the article WILL. Of significance for both testate and intestate succession, however, is the question whether a person's estate shall pass undivided to one person or whether it should be divided among several takers. This issue has been especially important in the history of Anglo-American law, where it is usually referred to as the problem of primogeniture. However, the term is too narrow, because the sole heir need not necessarily be the eldest son (primogenitus).

Under the system of ultimogeniture, which existed for instance in parts of England as the custom of Borough English (*q.v.*), or under the German National Socialist law of 1933, the person favoured was the youngest son; under the systems of seniorate or juniorate it would be the oldest or youngest member of the family; under that of majorate or minorate, it would be the oldest or the youngest person standing in equal degree of consanguinity to the decedent. There have also been cases where certain lands have been reserved to the second-born son and his line (secundogeniture) or the third-born and his line (tertiogeniture).

In England, undivided inheritance was applied to real estate, but not to personal property. The distinction between the two kinds of property was important in the struggle for power between church and state.

In medieval England, the organization of society in general, and of the army and the public offices in particular, was based upon the distribution of the ownership of the land, over all of which the king was lord paramount. The church, on the other hand, concerned itself with divine worship, the care of the sick and the poor and the cultivation of learning and the arts. After the Norman Conquest a compromise was worked out between the king and the church, under which the royal courts exercised jurisdiction over real property, while personal property was to be the concern of the ecclesiastical courts. Until 1926 descent to real property thus was subject to rules different from those applying to the distribution of personal property. For the former, the common-law courts developed a system which tended to maintain the existing military and social order through unpartitioned descent of land to one heir rather than division among several co-heirs, and through reluctance in admitting freedom of testation. Under the canons of descent the freehold real estate descended undivided to a single heir, who among several relatives of equal nearness to the ancestor was determined by the rules of preference for males and of primogeniture. Among several children the eldest son thus excluded all daughters and younger sons. If the decedent was not survived by issue, the real estate descended undivided to the collateral heir, who would be the eldest brother or,

if there were no brothers or sisters surviving, would be determined by the rule of ancestral estate, under which real estate that had come to the decedent from his father reverted to his father's line of the family, and real estate descended to him from his mother's side reverted to her line.

As to personal property, the ecclesiastical courts, however, favoured freedom of testation which allowed a decedent to leave part of his property to the church for the promotion of its manifold activities. In the case of intestacy, the church favoured equal distribution among relatives of equal nearness to the decedent, especially children. It thus applied the rules which had been laid down in the *Corpus Juris Civilis* by the Roman emperor Justinian and which were ultimately codified in England in the Statute of Distribution of 1670. Under these rules the estate was equally divided among the children of the decedent, or, if he was not survived by descendants or parents, among the decedent's brothers and sisters and their children and, in default of such relatives, among the next of kin of equal degree of consanguinity. A surviving husband or wife was to receive one-third or one-half of the personal estate, depending upon whether or not the decedent was survived by descendants. The problem about which the two sets of courts differed, namely, whether an inheritance should be split up among several co-heirs or pass undivided to a single heir, has, of course, not been limited to England.

Unpartitioned inheritance has indeed occurred in the most diverse civilizations. It has been reported from the Hottentots of southwest Africa, the Maori of New Zealand, from the Tonga Islands, from parts of China, from Siberia, as well as from parts of western Europe. Why and how primogeniture became the common-law system of inheritance of freehold real estate is not sufficiently known. Certain it is, however, that its existence favoured the needs of feudalism, in which the ownership of a parcel of land tended to be connected with a public office or with military duties that could not be well divided among several people. At the peasant level, holdings tended to be too small to allow a partition without destroying a family's basis for making a living and thus producing a result equally obnoxious to peasant and landlord. Attempts to avoid physical partition by a sale of the land and division of the proceeds were impracticable in a society in which it was considered important to preserve family ownership of the farm and in which money was not readily available. Partition was also likely to result in confusion regarding the services the peasants were bound to render to the landlord. In spite of these circumstances undivided descent of land to one heir never was the exclusive system of the European peasantry. It became, however, the almost universal system among the nobility, who were anxious to preserve intact the family wealth. In order to achieve this purpose it became necessary, after alienability of land and freedom of testation had developed, not only to establish unpartitioned descent as the rule of intestate succession but also to "entail" the land; *i.e.*, to prevent the owner from selling, giving away or encumbering the land, as well as from disposing of it by will (*see* ENTAIL). The success of such efforts depended on changing political constellations. In England varying legal devices were used from the 13th century on. After its invention in the 17th century the so-called strict family settlement became the principal device, while on the continent the fideicommission of late Roman law was adapted to serve the purpose. The political power secured in this way to the nobility and gentry enabled it, as the necessary counterpart of primogeniture, to secure for the younger sons the lucrative positions in the church, the army and, on the continent, the expanding bureaucracy. In the 18th century the system was attacked both by the supporters of democratic ideals and the economists of the classical school. To the latter entails were objectionable because they not only stood in the way of mortgaging the land for purposes of improvement but also because inalienability prevented its coming into the hands of the most efficient cultivator. The place where the system was to fall first was the British colonies in New England, and in the course of the American Revolution it was swept away also in the other states. In Europe, the decisive attack was launched by the French Revolution, and in the Napoleonic Code care was taken to prevent its re-establishment. Not only were all descendants or other relatives of equal degree to take equally in intestate succession, but by giving each child the right to a minimum share it was made impossible for the testator to give all to one child.

In England, the main object of the economists' attack upon settlements was removed, when through a series of successive statutes, especially the Settled Land act, 1882, settled lands were gradually restored to the market; life tenants were thereby given the power under certain circumstances to mortgage or sell the land. Stocks and bonds, which had meanwhile become the form of wealth more important than land, could, and still can be, tied up by means of a trust, but through the impact of heavy death duties this power has now been restricted. As the rule of intestacy primogeniture was abolished by the Administration of Estates act, 1925. (*See* also REAL PROPERTY AND CONVEYANCING, LAWS OF.)

On the continent, equal division among descendants and other relatives in equal degree became the general rule in the codes of the 19th century, but in certain countries, especially Austria and Germany, possibilities of entail lingered on as a privilege of the nobility until the revolutionary events of 1918. In the 19th century, a new argument came to be used, however, in favour of unpartitioned inheritance of land. First in France, and then in central Europe and Scandinavia, it was argued that through the splitting up of holdings in consecutive cases of succession, agricultural holdings were being diminished below the size necessary to provide a living for a family, and that the old peasantry was thus in danger of being driven from the land, which could then easily fall into the hands of speculators without traditional ties of blood and soil. The movement succeeded in the enactment of special laws on farm inheritance in sections of Austria, Germany and Scandinavia; while providing unpartitioned inheritance in the case of intestacy, most of these laws left unimpaired the power to provide for multiple succession by will and the power of alienation by sale. More radical was the farm inheritance law that was enacted in Germany in 1933 as one of the earliest measures of National Socialism. It provided not only undivided inheritance, as a general rule by the youngest son, but also forbade partition by will and even the sale of the farm or its encumbrance by mortgage. The peasantry was to be secured as a social class living on the soil, removed from the vicissitudes and temptations of a market economy. In order to secure maximum production, it was found necessary, however, to allow the state to remove an inefficient holder. The law was repealed upon the collapse of the National Socialist regime, but statutes attempting in milder ways to counteract the partitioning of farmsteads have been re-enacted. Even in France, the civil code was amended by successive laws of 1938, 1940, 1943 and 1955, so as to postpone, at least temporarily, the physical partition of a peasant holding.

INJECTOR, a device for injecting liquid fuel into an internal-combustion engine; also an apparatus for injecting feed water into a boiler.

In diesel engines fuel must be in highly atomized form for proper combustion. Usually this is accomplished with a plunger and cylinder arrangement (solid injection) which forces accurately measured amounts of liquid fuel into the combustion chambers through atomizing nozzles; compressed air (air injection) is sometimes used in place of a plunger. These injectors are widely used in such diesel equipment as railroad locomotives, trucks, buses, earth movers, ships and stationary power plants, and are sometimes found in aircraft and motor truck spark-ignition engines.

Boiler feed water injectors employ a high velocity steam jet to force water into the boiler. Because it was difficult to believe that boiler steam could force both itself and the feed water back into the boiler, the introduction (1859) of such injectors by their inventor, Henri Giffard, created great interest. They can use exhaust steam at atmospheric pressure to deliver feed water at 150 lb. per square inch. The principle is similar to that employed in the ejector (*q.v.*). In mixing with the relatively cold feed water, the steam condenses, imparting most of its momentum to the water. The kinetic energy associated with the resulting high velocity is converted to pressure in a convergent-divergent passage, delivering the water to the boiler. Now almost completely replaced by centrifugal boiler feed pumps, such injectors are primarily of historical interest.

See L. C. Lichty, *Internal-Combustion Engines* (1951); Terrell Croft (ed.), *Steam Power Plant Auxiliaries and Accessories* (1922). (RD. A. BR.)

INJUNCTION, an order of the court in civil proceedings requiring a party to those proceedings to do or not do a specified act or acts, disobedience to the order being punishable by imprisonment for contempt of court. An injunction is prohibitory if it forbids the doing of an act and mandatory if it orders an act to be done. Each type of injunction may be perpetual or interlocutory. A perpetual injunction is granted only on the final conclusion of the proceedings, and it operates either in perpetuity or for some stated period; *e.g.*, the duration of a lease. An interlocutory (interim or temporary) injunction is normally granted until the hearing of the action or for some lesser period, and is intended to preserve the *status quo*, or prevent irreparable harm, until the case can be fully heard.

ENGLAND

Origin.—By the end of the 14th century the court of chancery had begun to grant injunctions; and although later the common-law courts acquired jurisdiction to issue injunctions, the remedy has always been recognized as essentially an equitable remedy. The basis of the intervention of equity was the inadequacy of the remedy at law. The usual remedy at common law was an award of damages, and where this would sufficiently protect the plaintiff, equity would not intervene. But often an award of damages will not fully protect the plaintiff, as where the defendant intends to continue a trespass or a breach of covenant, and in such cases equity became increasingly ready to grant an injunction. The equitable origin of injunctions is manifest in a variety of ways. Equity acts *in personam*, and an injunction, supported by the threat of committal to prison for any breach, exemplifies equity acting on the person. Again, in most cases the remedy, like other equitable remedies, is discretionary. At law, a plaintiff who proves his case is entitled to damages; in equity, the court in the exercise of its proper judicial discretion may refuse an injunction to such a plaintiff; *e.g.*, if he comes to the court with unclean hands or is guilty of unreasonable delay. Yet again, the jurisdiction, being equitable, has always been exercised by the judge or court and not by a jury.

Principles.—The principles thus established by equity remain the basis of modern law. The Common Law Procedure act, 1854, empowered the common-law courts to grant injunctions in certain cases; the Chancery Amendment act, 1858, authorized the courts of equity to award damages in lieu of an injunction; and when the Judicature act, 1873, fused the courts of law and equity into one supreme court, it empowered that court to grant all remedies, legal or equitable (*see* now Judicature act, 1925, ss. 18, 37, 38). Nevertheless, the main principles upon which injunctions are granted or refused remain unchanged. In the case of perpetual injunctions, these principles may be summarized as follows: (1) Damages must be an insufficient remedy. (2) The grant of an injunction is usually discretionary, and so the plaintiff must establish sufficient grounds for the court to exercise its discretion to grant an injunction. Circumstances that may point against the grant of an injunction include the smallness of the damage suffered by the plaintiff, the cessation of the acts complained of, any undertaking offered by the defendant to abstain from the acts or mitigate their consequences, and the impracticability of compliance with the injunction, as where it is sought to preserve some trees and they have already been cut down. However, in one class of case the plaintiff may obtain an injunction as of right, namely, to enforce a negative restrictive provision in a contract; *e.g.*, a covenant not to build on land; for here the court merely enforces what the parties have expressly agreed. (3) The plaintiff must establish that some legal or equitable right of his is being invaded. It is not enough for him merely to show that he will suffer great inconvenience, as where his neighbour builds a wall obscuring the view, or gives his house the same name as that already borne by the plaintiff's house; for there is no legal or equitable right to the exclusive use of the name of a private residence. However, it suffices if the injury to the plaintiff's rights is merely threatened, for the court has jurisdiction to grant an injunction *quia timet* ("because he fears"); but a high probability of irreparable injury must usually be established, as when the sovereign of a foreign country shows that the defendant is about to manufacture spurious banknotes for that country. (4) The plaintiff must not have disabled himself from applying to the court, as by long delay or by inequitable conduct. Thus no injunction to restrain a breach of contract will be granted at the suit of a plaintiff himself in breach of that contract.

In the case of interlocutory injunctions, these principles can be applied only in a modified form, since the rights of the parties have yet to be ascertained. If the plaintiff establishes that he has a *prima facie* case in his action, he will usually obtain an interlocutory injunction if the balance of convenience favours it; the court will normally tend to preserve the existing state of affairs until the trial, and prevent any irreparable injury occurring. An interlocutory mandatory injunction is rarely granted, though it will be if the defendant tries to steal a march on the court, as by hurrying on with building an obstruction to a right of light after receiving notice of proceedings to enforce the right. In cases of urgency an interlocutory injunction may be obtained very speedily: an application may be made *ex parte*, supported by evidence on affidavit, as soon as the writ is issued. Such injunctions are usually granted only until the defendant can appear and present evidence, and so enable the court to decide whether or not to continue the injunction, with or without modifications, until the trial. No interlocutory injunction will be granted, however, unless the plaintiff gives an "undertaking in damages"; *i.e.*, a promise to pay damages for any loss caused to the defendant if it ultimately appears that the injunction was wrongly granted. Further, the court may impose limitations or restrictions on the operation of an injunction or suspend its operation for a period, as where immediate compliance would be impossible.

Range.—Injunctions may be granted in a wide range of cases. For example, an injunction may be granted to restrain a breach of contract, such as a contract against engaging in a competing business, or not to carry on any trade in a house; the commission of a tort, such as a nuisance or a libel; a breach of trust, such as selling trust property at an undervalue; an injury to property, such as erecting a wall standing on the plaintiff's land; wrongful expulsion, as from a club or trade union; the wrongful disclosure

of confidential information, as by a solicitor revealing his client's secrets; wrongful passing-off, as where one manufacturer dresses up his goods so as to resemble those of another; and infringements of patents, registered designs and copyrights. These examples, though important, are not exhaustive; an injunction is not only one of the court's most powerful weapons but also one of the most flexible. An individual cannot, however, obtain an injunction restraining a breach of some statutory duty unless some right of property of his is being injured. The attorney general, as representing the public, may obtain an injunction in any such case, even if the statute has duly provided a penalty for breach of the duty; thus such an injunction has been granted against an omnibus proprietor who, refused a licence to run his buses, nevertheless found it profitable to run them and repeatedly pay the fines prescribed by statute. (R. E. My.)

UNITED STATES

In the United States, despite the administration in most states of law and equity by a single court, the injunction retains its essentially equitable character and, as in England, covers a wide spectrum of types of injurious or potentially injurious conduct. The most significant developments have taken place in connection with labour disputes, government regulation and the protection of constitutional rights.

Labour Injunctions.—In the United States, beginning in the 1870s when many railroads were in the hands of receivers and thus administered by the courts, strikes were regarded as an obstruction to the courts, and injunctions were widely used to restrain various acts. Beginning in 1884 injunctions were issued in labour disputes not involving receiverships. When the U.S. supreme court gave its sanction to the use of the injunction in *In re Debs* (1895), it soon became an established weapon in the strategy of industrial conflicts. Its effectiveness in strikes is due largely to the procedure involved. It is only after trial and entry or denial of an injunctive decree that there is an adjudication of the merits, but in a strike situation, the restraining order and temporary injunction have the effect of bringing about a disposition of the strike so that the case seldom goes to final decree. The result is a determination of rights of basic character without a trial on the merits. In most cases the situation is handled through affidavits. The absence of oral testimony and cross-examination removes the principal safeguards in the fact-finding process, and the opportunity to correct error by appeal is extremely narrow and seldom exercised. Moreover, elaborate and ambiguous injunctive decrees reaching far beyond outlawed excesses and frequently barring trade union activities of a legitimate character have been entered. Dragnet decrees of this type were the rule rather than the exception.

The abuses in connection with the injunctive process in labour disputes resulted in a demand for legislation. The Clayton act, passed by congress in 1914 and designed to restrict the jurisdiction of federal courts to issue injunctions, was construed by the U.S. supreme court as "merely declaratory of what had always been the law and the best practice in equity"; the injunction might still issue against picketing deemed unlawful by the court (*American Steel Foundries* v. *Tri-City Trade Council* [1921]) and against the secondary boycott (*Bedford Cut Stone Co.* v. *Journeymen Stonecutters' Assoc.* [1927]). Subsequent state legislation, following sec. 20 of the Clayton act, received a corresponding construction (*Gevas* v. *Greek Restaurant Workers' Club* [1926]). Sec. 22 of the Clayton act granted the right of jury trial in proceedings for indirect contempt, where the act alleged to constitute the contempt is also a crime. This provision survived an attack based upon the doctrine that the power of a court of equity could not be restricted because inherent and derived from the constitutional grant of judicial power (*Michaelson* v. *United States* [1924]). The Norris-LaGuardia Anti-Injunction act of 1932 contained a detailed revision of equity practice in labour litigation which confined the discretionary jurisdiction of the federal courts in industrial disputes to very narrow limits, generally permitting injunctions only upon showing of violence or property damage not adequately dealt with by local authorities; withdrew the support of federal courts from anti-union agreements (so-called "yellow-dog" contracts); provided trial by jury for contempt growing out of claimed violation of an injunction; and sought to correct procedural abuses. More than half the states passed statutes patterned after this act. The effect of the Norris-LaGuardia act and the state statutes was to reduce substantially the use of injunctions in labour disputes.

The Labor Management Relations act of 1947, popularly known as the Taft-Hartley act, revived the use of injunctions in labour disputes. In addition to giving the National Labor Relations board the right to seek injunctions against employers and unions for certain defined unfair labour practices, a provision for an 80-day injunction was incorporated in the act. Federal district courts are authorized to issue such an injunction upon a finding that the threatened or actual strike affects an entire national industry, or a substantial part thereof, and imperils the national health or safety. The proceeding may be instituted by the attorney general upon direction of the president after a report of a board of inquiry which the president is empowered to invoke whenever he is of the opinion that a strike or lockout will endanger the nation. At the end of a 60-day period from the inception of the injunction, the board of inquiry is required to report to the president the current position of the parties and the efforts toward settlement. Within 15 days thereafter, the National Labor Relations board is required to take a secret ballot of the employees involved in the dispute on the question of whether they wish to accept the final offer of settlement made by their employer and to certify the results to the attorney general within 5 days. Upon certification of the results, or upon settlement, whichever happens first, the attorney general must move to dismiss the injunction and the court is required to do so. Thereafter the president has the duty of making a full report to congress with recommendations for appropriate action. The supreme court has upheld the validity of these provisions. (*See* also Labour Law: *United States.*)

Government Regulation.—The broadest extension of the injunctive remedy has been in the field of governmental regulation. Many federal and state statutes specifically authorize the use of the injunction as an alternative to seeking a criminal conviction. In the enforcement of federal statutes, particularly in the area of regulation of business, injunctions are sought with far greater frequency than criminal penalties in order to secure effective compliance. The injunction has been most effectively used in the enforcement of antitrust laws, federal wage and hour laws, securities and exchange legislation, pure food and drug laws and many other regulatory statutes. Similarly, in the area of state law enforcement, injunctions have been used to bring about compliance with a great variety of state regulations. With regard to economic regulations, which embrace almost every phase of business and industry, criminal sanctions have obvious drawbacks. Effective enforcement would involve the bringing of numerous criminal cases, which, in turn, would result in overloaded court dockets. In addition, there is the added burden of presenting cases to grand juries and the problems of burden of proof. Moreover, the entry of a fine, the only criminal sanction available against a corporation, does not deter future violations. Particularly is this true where very large interests are involved. Fines imposed may be nominal compared with the substantial gains achieved by illicit conduct. These reasons for resort to the injunction are especially pertinent to regulations adopted during wartime and other periods of national emergency.

Constitutional Rights.—Protection of the rights of individuals as guaranteed by the U.S. constitution has been the object of an increasing number of injunction proceedings. In this field the courts have departed from the common-law requirements of a showing of injury to property. Injunctions have been permitted to prevent violations of the rights of free assembly and speech, violations of religious freedom and the denial of equal opportunity for education on racial grounds alone. The leading precedent establishing the rights of Negro students to education in a nonsegregated school was an injunction proceeding (*Brown* v. *Board of Education of Topeka* [1954]). The basis of granting relief is the actual or threatened violation by local or state authorities of rights guar-

anteed by the 14th amendment of the U.S. constitution. By way of implementing the elective franchise and to prevent denial of the right to vote on the ground of race, colour or other restrictions, congress has authorized the attorney general to institute injunction proceedings in the name of the United States to prevent such action.

Criticism and Change.—The use of the injunction has been the subject of substantial criticism and complaint. Peculiar to the United States federalist system is the problem of a federal court enjoining a proceeding in a state court and vice versa. The general principle is that no such injunctions shall issue; but being courts of concurrent jurisdiction the court that first obtains jurisdiction of the subject matter regards its authority as exclusive and employs the injunction in aid of this purpose. The friction that might result from a liberal use of the injunction in this way was foreseen at an early date, and in 1793 congress prohibited such use by the federal courts except in bankruptcy cases. The federal courts have, however, by a series of judicial decisions, established numerous exceptions to this broad statutory provision, such as in the field of constitutional rights.

A second ground of irritation concerned the use of the injunction by the federal courts to restrain the enforcement of state statutes on the ground of their unconstitutionality. An appeal from such action lay to the U.S. supreme court, but during the interim a single federal judge was able to set at naught the entire administrative authority of a state. A related problem is the use of the injunction against administrative acts of public officials, such as in the regulation of business, the collection of taxes and the fixing of rates by public utility commissions. While the injunction here has the advantage of raising questions of the validity of the administrative actions at an early date, the effect of such injunctions, which federal judges readily granted, was to impede seriously the activities of one branch of the government. These problems led congress, by a series of statutes beginning in 1910, to prohibit the issuance of such injunctions except by a court consisting of three judges, one of whom should be a judge of a court of appeal, and to provide for expediting an appeal therefrom to the supreme court. Another area of complaint, and one which has been voiced against the use of injunctions generally, is that the right to a trial by jury is not available, particularly with relation to contempt proceedings growing out of the claimed violations of injunctions. The Clayton act made provision for jury trials in certain contempt cases, and other federal statutes have imposed similar requirements. In the federal statute protecting the right to vote, defendants found guilty of criminal contempt, fined in excess of a stipulated amount or imprisoned in excess of a specified number of days, are given the right to a new trial before a jury. (A. EN.)

Symons, vol. 4–5 (1941).

INK, a liquid or paste that contains pigments or dyes and is used chiefly for writing or printing. An ink consists of two fundamental components: (1) a pigment or dye; and (2) a liquid, called the vehicle, in which the pigment or dye is dispersed. Ink may contain other ingredients that adapt it for special uses. This article discusses first writing ink and then printing ink.

WRITING INK

Inks used for writing are solutions of colouring material and other substances in water. The first inks, dating from about 2500 B.C. and used in the early Egyptian and Chinese civilizations, consisted of lampblack ground with a solution of glue or gums. This mixture was molded into sticks and allowed to dry. The sticks were mixed with water before use. Coloured juices, extracts and suspensions of many plant, animal and mineral substances have been used as inks, including alizarin, indigo, pokeberries, cochineal and sepia. A soluble iron salt forms a dark-coloured solution with an extract of tannin. Such mixtures have been used as writing ink for many centuries and are the basis of modern blue-black inks.

General Properties.—Writing ink should leave a neat, legible mark. The marks left by a permanent ink should remain legible after soaking in water and after exposure to strong light. The ink mark should not accelerate deterioration of the paper. The ink should dry fairly quickly on paper and not smudge. It should not produce a feather-edged line; it also should not penetrate through the paper or offset onto the adjacent sheet. The ink should have good writing qualities, including free and even flow from the pen without flooding or clogging. It should resist drying and thickening on the feed and point of fountain pens. The liquid should remain stable on standing; it should not form scum or sediment or permit the growth of mold or other microorganisms. It should be inert to steel pens and to the rubber, plastic and other parts of fountain pens.

Types and Contents.—Numerous special materials, in addition to the colour, are added to inks to modify their properties for the purposes outlined above.

Blue-black inks usually contain ferrous sulfate as the iron salt. At one time the tannin for inkmaking was obtained by extracting oak galls with hot water as part of the process. In the United States, however, most inkmakers adopted purified gallic and tannic acids. A small amount of mineral or organic acid is usually added. Such a solution has a light bluish-black colour, and the writing on paper is faint initially but on standing becomes darker and insoluble in water. The latter property gives the ink its permanent quality. If the record becomes wet, the characters do not wash out but instead remain legible. Blue dyes are added to blue-black inks to enhance the appearance and to make the writing legible at the outset. The following formula is from Federal Specification for Writing Ink, no. TT-I-563b:

Gallic acid crystals	5.0 g.
Ferrous sulfate crystals	7.5 g.
Tartaric acid	1.0 g.
Soluble blue (Colour Index no. 707)	3.5 g.
Distilled water, to make (25° C.)	1 l.

Aqueous extracts of logwood with various metal salts, principally those of chromium, were extensively used as inks for many years but by mid-20th century they were little used in the United States. A small amount of ink that uses colloidal Prussian blue for the colour has been produced.

Coloured inks contain soluble dyes as the sole colouring matter. Such inks are for school and home and such business use as does not require a permanent record because the writing on paper fades in strong light and washes out if immersed in water. However, the writing on paper will last for many years if protected from such deteriorating effects.

Washable inks are dye-base inks that may be washed from washable fabrics more readily than permanent inks. A typical washable ink has the following formula:

Soluble blue (Colour Index no. 707)	5.0 g.
Glycerol	10.0 g.
Thymol	0.5 g.
Water, to make	1 l.

India ink is a dispersion of carbon black in water. Numerous substances have been suggested for stabilizing the suspension, including various alkaline solutions, shellac dissolved in borax solution, soap, gelatin, glue, gum arabic and dextrin. It is used mainly as drawing ink, though some is used as writing ink.

Manufacturers sometimes add optical bleaches, or "white dyes," to writing inks. These colourless substances leave a deposit on paper that fluoresces under ultraviolet radiation after the visible portion of the writing has been decolourized by ink eradicator or by soaking in water. This permits the eradicated record to be read.

Manufacture.—The manufacture of writing ink consists of purifying the water by distillation or deionization, dissolving the ingredients in large tanks, clarifying the resulting solution by decanting, filtering or centrifuging, and packaging.

The packaging is usually done by a series of automatic machines that put the right amount of ink in each bottle, put on caps and screw them down, attach the label and insert each bottle in a carton. Such an automatic production line can produce more than 50,000 small bottles per eight-hour day. Economically, the pack-

age and the handling, storing and shipping are by far the most important parts of ink manufacture, because they represent a large fraction of the total cost.

In the mid-1960s, an increasing amount of writing ink was being marketed in fountain pen refill cartridges.

Ball-point and Other Special Writing Inks.—In a ball-point pen the ink is transferred from the reservoir to the paper by a rotating ball held in a socket at the writing tip of the pen. Ball-point pen inks consist of pigments, or more frequently dyes, dispersed in a nonvolatile solvent consisting usually of glycols or glycol derivatives. Since ball-point pens lay down on the paper a very thin line of ink, the concentration of the dyes must be 20 or more times that used in writing inks.

Stamp-pad inks, *i.e.*, those used with rubber stamps, are solutions of dyes in glycerol or a glycol and water.

Inks for various duplicating processes contain a high concentration of colouring matter.

Inks for numbering and canceling machines that use metal type are dispersions of dyes or pigments, or both, in an oil base.

(R. S. Cy.)

PRINTING INK

Printing inks are used in printing on paper, parchment, cellophane, Celluloid, metal, plastic, leather, wood, cork, rubber, cloth, glass, ceramics and similar materials. Printing inks generally are less fluid than writing inks, in most cases possessing a consistency resembling paint. Printing ink is applied to a surface as a light liquid film that dries to a solid after imprinting. The important characteristics of an ink are its colour strength, opacity or transparency, body or working properties, and drying properties. The viscosity, density, volatility and diffusibility of ink are varied so as to adapt the ink to the printing process employed, the speed of the press and the material printed upon.

Origin and Development.—In Asia, where the Chinese experimented with printing (*q.v.*) at least 1,000 years before the time of Johann Gutenberg, printing inks were made from plant substances mixed with coloured earths and soot or lampblack. When Gutenberg invented printing in Europe in 1440, inks were still being made by mixing varnish or boiled linseed oil with lampblack. Such inks continued in use with little modification for more than 300 years.

The first patent for making coloured inks (*i.e.*, those other than black) was issued in England in 1772 and by the latter part of the 19th century the application of driers made possible the use of a wide variety of pigments in the manufacture of coloured inks. However, the method of inkmaking differed very little from the processes used in the time of Gutenberg.

Later developments included the use of varnishes of varying degrees of stiffness to provide inks for different kinds of paper and different kinds of presses. With the introduction of web-fed newspaper presses, mineral oils (*i.e.*, those from petroleum) began to replace varnish as the ink vehicle. Despite the gradual changes that were made in the composition of ink over three centuries, it was not until the beginning of the 20th century that inkmaking became a complicated industrial process based on chemistry.

Types and Contents.—*Variables.*—Inks must be compounded to take into account the surface to be imprinted, the printing process to be used and customer requirements such as colour, opacity or transparency, brilliance, permanency (fastness to light), surface hardness, pliability, wettability and freedom from odour or contaminants. The ink manufacturer also must consider the type of manufacturing equipment he will use, the length of the manufacturing process and the amount of handling the ink will be subjected to during processing or in transit to the customer. Because of the large number of variables to be considered (usually about ten), the compounding of ink is an intricate process. Since some variables depend upon the requirements of the user, manufacturers frequently mix an ink to a special formula agreed upon by the user and the inkmaker. Despite the wide use of custom-formulated inks, stock inks are available and can be ordered by name or code number.

The three main methods of printing are letterpress (or relief), which uses raised surfaces; intaglio (gravure), in which depressed or incised wells carry the ink; planographic (offset lithography), in which ink is deposited on grease-treated printing areas while the nonprinting parts, which hold water, reject the greasy ink. (*See* LITHOGRAPHY.) Other methods include screen printing, in which the areas to be printed are inked in by brush, dauber, squeegee or roller applied over open or mesh-covered cutouts (*see* SILK SCREEN PRINTING); and electrostatic, in which ink in mist form is pulled through a shield or mask by an electric charge to form the desired image. Inks suited to one process of printing may not be suited to another process. For example, ink for letterpress need not be water-repellent, although this is a primary requisite in planographic ink. Ink for intaglio printing must be of a thin consistency that will permit it to be lifted from the wells whereas ink used in screen printing can be much thicker.

Fluid Ingredients.—The two basic ingredients of printing ink are the vehicle (also called the body) and an organic or inorganic pigment or dye (also called the colorant). Inks used for low-speed letterpress printing consist of carbon black mixed with a heavy varnish and a drier. The purpose of the drier is to reduce the drying time.

For more complex methods of printing, especially at high speeds, numerous other vehicles and pigments are used along with a wide variety of modifiers or additives that make the ink perform in the manner desired and also produce the appearance and durability required. Specially formulated inks may contain as many as 15 different ingredients.

Regardless of the printing method used, the speed with which the ink dries is important. Drying may occur by oxidation, penetration (absorption), evaporation, gelation, coagulation, precipitation or polymerization. The type and speed of drying depend upon the vehicle, which may be linseed varnish, alkyd or other synthetic resins, mineral oil or other petroleum derivatives, alcohol or glycol compounds, hydrocarbons, shellac, lacquers and oils such as castor, tung, soya, cottonseed or perilla. Vehicles may be used separately or in combination with each other. They may be blended by dissolving, cooking, or mixing in an ink mill. Driers made of salts of cobalt, lead and manganese have the property of absorbing oxygen from the air and thus speeding up the formation of a film over the surface of the ink. Special additives may be included to prepare inks for special uses; for example, synthetic resins that dry quickly when heated are added to produce heat-set inks (*see* below) or a mixture of glycols and resin is added to produce moisture-set inks. Because they penetrate rapidly into newsprint, inks made with a mineral oil base are generally used in printing newspapers on high-speed presses. Intaglio inks are composed of petroleum naphthas, resins and coal-tar solvents; the intaglio process is used chiefly in printing rotogravure newspaper supplements and cartons, labels and wrappers. Cellophane, glassine and other plastic materials are usually printed with aniline (or, flexographic) inks, which contain methyl alcohol, synthetic resins and shellac.

Pigments and Colorants.—Pigments used in printing inks were derived originally from mineral, vegetable and animal sources in nature. Most natural pigments can now be duplicated chemically by synthesis and compounding; most modern dyes, for example, are derived from coal tar.

Prominent among the mineral pigments found in nature or obtained from natural sources is ultramarine blue, made from powdered lapis lazuli, a complex silicate containing sulfur (*see* ULTRAMARINE). Other pigments made from earth substances include sienna, which derives its colour from oxides of iron and manganese and is brownish-yellow when raw and orange-red or reddish-brown when burned; ochre (*q.v.*), an impure ore of iron that is found in both red and yellow colours; umber, which provides a brown-red-yellow hue, the saturation and brilliance of which may be controlled by burning; and Indian red, which is found in nature or may be produced by calcining iron salts. Although natural mineral pigments are more stable and therefore are more resistant to deterioration by light, heat and moisture than are pigments produced synthetically, they also are more abrasive and tend to cause the printing surfaces to wear. Synthetic pigments are less abrasive since they are produced by filtration, whereas milling and grinding

are used in processing natural pigments.

Pigments from vegetable sources include indigo (*q.v.*), a blue dye obtained from the leaves of several plants; gamboge (*q.v.*), a reddish-yellow gum resin from certain tropical trees; and yellow lake, derived from the inner bark of the black oak tree.

Pigments from animal sources include those obtained by burning vegetable oils to produce carbon black (*q.v.*); Indian yellow, derived by evaporating the urine of camels or cows; sepia (*q.v.*), a dark brown obtained from the secretions of the cuttlefish; carmine(*q.v.*), a red or purplish-red pigment obtained from cochineal (*q.v.*), which in turn is a red dye obtained from female scale insects. (*See* also DYES AND DYEING.)

Colour and Covering Characteristics.—Colour printing in magazines and similar publications is achieved through the overlaying of three primary colours—yellow, red (magenta) and blue (cyan)—and black by means of toned or screened plates. When the colour and black plates are printed in sequence on a surface, the result is a series of intermingled or overlapping dots of the separate colours, shaded with black. (*See* also PHOTOENGRAVING.)

In colour inks, the shades (light to dark) and hues (colour strength) of the basic spectrum colours (red, orange, yellow, green, blue, indigo and scarlet) are of almost unlimited number. Each colour is available in about 100 shades or hues. However, efforts to describe and catalogue the colours and shades scientifically have not won general acceptance; consequently, colours usually are matched by eye comparison in the printing industry.

When inks are matched or compared, their abilities to cover a surface must be considered along with their light reflective characteristics (colour). The covering qualities of inks vary with the colour. For example, a pound of high-grade black ink will cover 100 sq.in. of surface for approximately 1,000 impressions. A pound of blue ink will cover approximately 90 sq.in. of surface in 1,000 impressions; a pound of red will cover 80 sq.in.; a pound of yellow, 70 sq.in.; a pound of white, about 60 sq.in.

The inks used in printing on rough or coloured papers differ from those used for printing on smooth white papers. For example, a transparent red ink designed for use on white paper will produce a brown colour if printed on green paper. Also, almost twice as much ink is required when printing on rough paper as is used in printing on a smooth white paper.

Special Inks.—Although, as has been mentioned, almost all inks are compounded for a specific purpose, the term special is applied to many inks used outside what is generally called commercial, or job, printing. The number of special inks is quite large; examples are those that are heat-set, cold-set, steam-set, metallic, fluorescent and magnetic.

Heat-set Inks.—Inks of this type are stable at room temperature but solidify (dry) when heated. On the press they are changed from a semiliquid to a solid form by heaters, burners or steam-heated drums. Heat-set inks are useful on high-speed presses or in other instances in which slow-drying inks would produce smearing or unwanted offset impressions. Some heat-set inks are manufactured from finely pulverized polyvinyl chloride mixed with a plasticizer and a solvent. Drying temperatures may exceed 350° F. (about 176.7° C.). After heat-set ink has been dried by heating, the paper that has been printed upon must be passed over cooling rollers to cool it to near-normal temperatures.

Cold-set Inks.—A variant of heat setting is cold setting, in which ink is applied at an elevated temperature and then solidifies upon cooling. Such inks are called cold-set inks.

Steam-set Inks.—Steam-set inks, which are made with a glycol-resin vehicle, dry upon contact with moist steam through coagulation and penetration. Such inks usually are applied as a vapour or mist. The drying rate of steam-set inks may be controlled by using different glycols and different resins. If the paper or cardboard being printed upon is porous, steam-set ink can be dried by maintaining a high relative humidity in the pressroom.

Metallic Inks.—Many kinds of metallic inks are used in printing on packaging and metal sheets or foil. Such inks consist of microscopic flakes of metal suspended in an appropriate vehicle. They may be compounded to emphasize a colour as well as the metallic sheen, or to resemble gold, silver or other metals. Gold inks are usually made with bronze powder but in some instances (*e.g.*, in stamping book covers) gold leaf may be used. Silver inks are ordinarily compounded of aluminum powder.

Fluorescent Inks.—When a high degree of colour brilliance is desired, fluorescent inks are used. Such inks, which also are called optical brighteners, absorb ultraviolet and other nonvisible forms of radiation and emit this energy as visible light. Fluorescent ink pigments that are three to five times brighter than ordinary colouring materials can be made from zinc, cadmium or strontium sulfide. Phosphorescence may be provided by blending sulfide pigments with radioactive uranium salts or activated barium sulfate. Fluorescent inks retain their brightness for 30 days to one year, depending upon the extent of exposure to light. Consequently, a protective coating is sometimes added to prolong the period of fluorescence. (*See* also LUMINESCENCE.)

Magnetic Inks.—Checks and other business forms that are sorted in electronic scanning or sensing devices are imprinted with magnetic inks. The inks transfer signal patterns to machines that automatically punch cards, perforate paper tapes or record signals on magnetic tapes. Magnetic inks contain finely ground particles of iron oxide or similar materials suspended in vehicles of high viscosity.

Manufacturing Process.—In the first step in manufacturing printing ink, the pigment or colouring matter is mixed with the vehicle by stirring, whirling or churning. This mixture is then ground in a mill in which a thin film of the mixture is forced between steel drums or rollers. The rollers, turning at various speeds and clearances, break the pigment into particles of microscopic size that become saturated, or wet, with the vehicle. The mixture is passed through the mill from three to ten times, depending on the hardness or softness of the pigment and its suspension or wetting qualities. During the mixing, or milling, process or at a later stage, driers and other modifiers are added to complete the formulation.

The above description applies primarily to the manufacture of inks in which natural colourants are used. When synthetic pigments (*e.g.*, those made by mixing two or more chemical solutions) are used, the tiny particles of pigment may be filtered out and mixed with the vehicle in machines devised especially for this purpose. Any water remaining from the chemical solution is flushed out and drained off in the mixing process. Chemically produced pigments normally require less milling or grinding than natural pigments.

Consumption and Research.—The amount of ink used on a printing job may vary from a fraction of an ounce for a small run of letterheads or calling cards to as much as 200,000 lb. for the Sunday edition of a metropolitan newspaper. In a commercial job-printing plant of medium size, about 30,000 lb. of ink is used annually and in a large book or magazine plant it may be ten times that amount. To print all of the newspapers in the United States in a single weekday requires between 600,000 and 700,000 lb. of ink.

Most large printing inks manufacturers conduct research. The National Association of Printing Ink Makers operates the Printing Ink Research institute at Lehigh university, Bethlehem, Pa.

INKBERRY (*Ilex glabra*), a North American shrub of the holly family (Aquifoliaceae), known also as evergreen winterberry, bearbush and Appalachian tea, native to sandy soil from Nova Scotia to Florida and west to Louisiana, mostly near the coast. It is a small shrub, two feet to six feet high, with leathery, evergreen, oblong, usually slightly toothed leaves; small white flowers, solitary or sometimes two or three together, borne on short slender stalks in the axils of the leaves; and small black berries (drupe), about ¼ in. in diameter, ripening in autumn. Among other plants called inkberry are the West Indian indigo berry (*Randia aculeata*) and the widely distributed pokeberry (*Phytolacca decandra*). The Australian or Queensland inkberry is *Mollinedia macrophylla*, a plant of the family Monimiaceae. *See* HOLLY; POKEBERRY.

INKERMAN, BATTLE OF, an engagement during the Crimean War (*q.v.*), was fought on Nov. 5, 1854, when Russian forces under General Dannenberg unsuccessfully attacked the Anglo-French army besieging Sevastopol. The Allied positions on a ridge lying between the Chernaya river and the Careenage ravine were attacked by two Russian columns: one in the north moved across the river to face the 2nd division supported by the guards brigade; the other, from Sevastopol, faced the light division on the west of the battlefield. The attack was supported by artillery on Shell hill to the northwest. In uncertain and foggy morning light the Russians surprised British forces who stemmed the advance by throwing themselves into action as soon as they became aware of the danger. This remained the pattern of the day. There were about 42,000 Russians in the field, but they were committed piecemeal and unimaginatively to a persistent action that centred around a stone strong point to the north of the Allied-held ridge. As the day advanced the British force grew in size until it reached 8,500, but the Russian final offensive would have been successful had it not been for timely French support sent by Gen. P. F. J. Bosquet. The Russians began to retreat about noon; Shell hill was in Allied hands and the battle over by about 1:30 P.M. Casualties were heavy: the Anglo-French exceeded 3,000 and the Russian were more than 10,000. The surprise of the Russian attack, the nature of the ground and the poor visibility all contributed to the engagement being a soldier's rather than a general's battle, for over-all direction was impossible. (D. M. Sc.)

INLAND MARINE INSURANCE: *see* MARINE INSURANCE.

INLAND SEA (SETO-NAIKAI), the body of water lying between the Japanese islands of Honshu, Shikoku and Kyushu. Its east-west length is approximately 250 mi. and its waters are easily navigable. The sea has an extremely irregular coast line and is dotted with hundreds of small islands. Entrance to the Inland sea from the Philippine sea and the Pacific ocean is by the Bungo strait and Kii strait. The narrow Shimonoseki strait at the western end leads to the East China sea. *See* JAPAN: *Physical Geography.*

INMAN, HENRY (1801–1846), U.S. painter of portraits, genre and landscape, was born in Utica, N.Y., on Oct. 20, 1801. Apprenticed to the painter John W. Jarvis at the age of 14, he left him after seven years and set up for himself. He was one of the organizers of the National Academy of Design in New York and its first vice-president (from 1826 to 1832). As a portrait painter he was highly successful both in New York and Philadelphia, and going to England in 1844, he had for sitters the lord chancellor (Cottenham), the poet William Wordsworth, Thomas Chalmers, Lord Macaulay and others. His American sitters included Pres. Martin Van Buren and Chief Justice John Marshall. Inman died in New York city on Jan. 17, 1846.

INN (ancient AENUS), a major right-bank tributary of the Danube, rises in the small lake Lughino in Graubünden (Grisons), Switz. Length 510 km. (319 mi.), drainage area about 9,923 sq.mi. Its first section, to the Austrian border, is the Engadine; the Oberinntal, above Zirl, is narrow; the lower Inn valley, which includes Innsbruck, is wide, except where the river has cut through the Limestone Alps at Kufstein. Entering Bavaria it crosses the Quaternary Rosenheim basin, then turns eastward along the Tertiary hills. After receiving the Salzach, its major tributary, it forms the Austro-German border to its confluence with the Danube at Passau. Because of the glaciers of its catchment area it has a pronounced glacial regime. The river is utilized for hydroelectric power with important plants at Kirchbichl, Wasserburg, Braunau, Ering, Obernberg and Schärding. (K. A. S.)

INNATE IDEAS, ideas supposed to be inborn in the human mind, as contrasted with those received or compiled from experience. The doctrine that at least certain ideas must be innate (*e.g.*, those of God, perfection and infinity), on the ground that no satisfactory empirical origin for them could be conceived, was widely held in the 17th century and had Descartes for its most prominent exponent. The theory took more than one form, some holding the naïve view that the human mind must from the start of the child's life have an explicit awareness of such ideas, others, more commonly, maintaining innate ideas in some implicit form, either as a capacity for formulating them, which remained dormant until suitable conditions for its actualization occurred in experience, or as a tendency, which again would require favourable conditions for its development. Descartes professedly adopted the last view, although his writings contain indications of the more naïve version; and, having at first maintained that only some ideas were innate (others being either "adventitious" or "factitious"), he was driven by his metaphysical dualism into concluding that all ideas were innate.

The whole doctrine was vigorously and effectively criticized by Locke in the first book of his *Essay Concerning Human Understanding*, where his main target was innate principles (supposed axioms, both theoretical and practical, of which the mind had inborn knowledge, as they had been implanted in it by nature), with as secondary target the innate ideas which were claimed as the terms of the principles. He refuted the arguments for the naïve form of the theory and showed that in its dispositional form the theory defeated its own object by making it impossible to distinguish between those ideas which were and those which were not innate. His refutation was undertaken by way of introduction to his own positive thesis, that all ideas are empirical, the only two sources being, in his own terminology, sensation and reflection. That he did not succeed in his thoroughgoing empiricism, even to his own satisfaction, he recognized in the case of certain key concepts, such as Substance, "which we neither have nor can have by sensation or reflection," and Cause, where he largely anticipated Hume's difficulties.

While Locke seems to have shared some of the assumptions of his opponents (*e.g.*, that if an idea is innate it cannot be wrong), he shows signs of recognizing, at least in the case of principles, that the philosophically important question was not one of genetic psychology, about origins, but one of logic, about the status and validity of an a priori or necessary proposition. Leibniz, in his criticisms of Locke, carried the matter further; and Kant, completing the distinction that Locke had begun, replaced questions about innate ideas with questions about a priori concepts, which he characterized in terms, not of their origins, but of their necessity as conditions of our experience of an objective world. (A. D. W.)

INNERLEITHEN, a small burgh of Peeblesshire, Scot., lies on the Leithen water, near its junction with the Tweed, 7 mi. S.E. of Peebles by road. Pop. (1961) 2,299. The town is flanked on the west by the hill fort of Caerlee and on the east by that of Pirn. The district is known to have been inhabited by Celtic peoples in 55 B.C. Its chief industry is the manufacture of tweeds, hosiery and other woolen goods, which, together with the fame of its medicinal springs, brought the burgh into prominence toward the end of the 18th century.

St. Ronan's well, known for centuries before Sir Walter Scott made it famous in his novel of that name, has a pump room and well house; however its mineral waters are now very little used.

Farther east, close to the village of Walkerburn, is Purvis hill with a remarkable series of terraces or earthen banks, the origin and purpose of which are unknown. Traquair house, or palace, on the right bank of the Tweed, is one of the oldest mansions in Scotland, the most ancient portion dating from the 10th century and the main block from 1642.

INNES, JAMES DICKSON (1887–1914), British landscape painter, noted for bold, flat masses of pure colour, was born at Llanelly, Carmarthenshire, Wales, on Feb. 27, 1887. In 1904–05 Innes studied at the Carmarthen art school; then he spent three years at the Slade school, University college, London. Works exhibited in 1907–08 showed him strongly influenced by P. Wilson Steer and W. R. Sickert.

Water colours by J. S. Cotman and J. M. W. Turner and John Constable's paintings were other formative elements, and Innes discovered his aptitude for water-colour landscape. In 1908, inspired by the sun-drenched Pyrenean landscape around Caudebec, Bozouls and Collioure, he adopted a brilliant palette. The next year he visited St. Ives (Cornwall) and Paris, and in 1910–13 he returned often to Collioure and visited Spain. Two expeditions to Wales in 1911–12 with Augustus John further shaped Innes' style. He then painted in oils and became interested in Japanese colour prints. Besides the English roots of Innes' art, parallels with Paul Gauguin and the *Fauves* can be perceived. Innes' delicate health failed rapidly and, after wintering in Morocco in 1913, he died at Swanley, Kent, on Aug. 22, 1914.

See Lillian Browse (ed.), *James Dickson Innes*, with an introduction by J. Fothergill (1946). (D. L. Fr.; X.)

INNESS, GEORGE (1825–1894), U.S. painter of landscapes in the romantic style, was born near Newburgh, N.Y., May 1, 1825. During his boyhood at Newark, N.J., he was interested in drawing but not in school or clerking, whereupon he was allowed a few lessons. There followed work with a map-engraving firm in New York city, an interval of country sketching and a brief study of painting under Régis Gignoux. About 1845 Inness established a studio in New York city and in 1846 exhibited at the National Academy of Design, New York. The next year friends made possible a stay of several months in Italy. Back in Newark, Inness married his first wife; she died about six months later. In 1850 he married a second time and made a second trip to Europe.

Inness became an associate of the National Academy of Design at 28, but was kept waiting 15 years for full membership. A third trip to Europe (1854) ended his initial period of experiment in subject and struggle against technical tightness. This stay abroad confirmed the already discernible releasing influence of the French Barbizon school led by Théodore Rousseau. It was through the two decades of his middle period (1855–74) that Inness ascended to the height of his powers. The famous and impressive "Peace and Plenty" (1865) remains exceptional in his work for physical dimensions; his more characteristic smaller canvases depict both far-reaching expanses and lesser areas intimately rendered. His increasing control over space relations and scale, drawing and colour was directed to achieving the idyllic and the tranquil; he often brought in storm clouds for the sake of their grays and blues, but he never let them break into tempestuous violence. Yet all the while his temperament continued stormy and passionate. He was interested in social questions, and argued heatedly for the single tax and for abolitionism, but the deepest effect on him and his art came from his conversion to Swedenborgianism. The beginning of the final period (1875–94) was marked by pictures with great concentration of feeling ("Evening at Medfield") and by others which foretold the later sacrifice of strength to vaporous colour ("Autumn Oaks"). For most of these latter years his home was at Montclair, N.J., and his studio in New York city, but his notable prosperity permitted frequent trips to distant places. As his nature mysticism intensified, his pictures volatilized into shimmering colour, frequently gorgeous in itself but no longer supported by form construction. During a trip to Scotland he died at Bridge of Allan on Aug. 3, 1894. His painter son, George Inness, Jr. (1854–1926), remained faithful to the practices of Barbizon and resisted Impressionism in obedience to his father's violently expressed convictions.

INNOCENT (Innocentius), the name of 13 popes and 1 antipope.

St. Innocent I (d. 417), pope from 401 to 417, was the son, according to St. Jerome, of Pope Anastasius I. During his papacy the siege of Rome by Alaric (408) took place; the pope was absent from Rome on a mission to Honorius at Ravenna at the time of the sack in 410. He maintained and extended the authority of the Roman see as the ultimate resort for the settlement of all disputes; his still extant communications to Victricius of Rouen, Exuperius of Toulouse, Alexander of Antioch and others, as well as his action on the appeal made to him by Chrysostom against Theophilus of Alexandria, are examples of his intervention. In Jan. 417 he made a decision on the Pelagian controversy, confirming the views of the synods of Carthage (for proconsular Africa) and of Mileve (for Numidia), which had addressed letters to him in 416. He died on March 12, 417, and in the Roman Catholic Church is commemorated as a confessor with St. Nazarius, St. Celsus and St. Victor, martyrs, on July 28.

Innocent II (Gregorio Papareschi dei Guidoni) (d. 1143), pope from 1130 to 1143, was a Roman by birth. His ability, pure life and political connections raised him rapidly to power. Made cardinal deacon of Sant' Angelo in Pescheria by Paschal II, he was employed in various diplomatic missions. Calixtus II appointed him one of the ambassadors who made peace with the empire and drew up the Concordat of Worms (1122); and in 1123, with his later rival Cardinal Peter Pierleoni, he was papal legate in France. On Feb. 13, 1130, Honorius II died, and on that night a minority of the Sacred College elected Papareschi, who took the name of Innocent II. After a hasty consecration he took refuge with a friendly noble from the supporters of Pierleoni, who was elected pope under the name of Anacletus II by a majority of the cardinals. Innocent refused to recognize the choice; by June, however, he was obliged to flee to France.

Much of Innocent's pontificate was spent in vindicating his title. He owed his success chiefly to the tireless energy of St. Bernard of Clairvaux, who at the council of Étampes swayed the French church in his favour (?Sept. 1130). In Jan. 1131, Bernard arranged a meeting between Innocent and King Henry I of England at Chartres. A similar lead was given to the German church by St. Norbert at the synod of Würzburg (Oct. 1130). In March 1131 Innocent met the German king Lothair at Liège and induced him to undertake a campaign against Anacletus. The German army invaded Italy in Aug. 1132 and, early in the following summer, occupied all Rome except the Leonine City, which was held by the Anacletans. Lothair was crowned emperor at the Lateran in June 1133, and Innocent gave him the territories of the Countess Matilda of Tuscany as a fief but refused to surrender the right of investiture. Left to himself Innocent again had to flee, this time to Pisa. There he called a council which condemned Anacletus. A second expedition (1136–37) of Lothair expelled Roger of Sicily (to whom Anacletus had given the title of king in return for his support) from southern Italy, but a quarrel with Innocent prevented the emperor's attacking Rome. At this crisis, in Jan. 1138, Anacletus died, and a successor elected by his faction, as Victor IV, resigned after two months. The Lateran council of 1139 restored

peace to the church, excommunicating Roger of Sicily; but an expedition undertaken against Roger ended in Innocent's being taken prisoner and obliged to recognize him. The pope supported Bernard of Clairvaux in his prosecution of Peter Abélard and Arnold of Brescia, whom he condemned as heretics.

The remaining years of Innocent's life were taken up by a quarrel with the Roman commune, which had set up an independent senate, and by one with King Louis VII of France, about an appointment. France was threatened with the interdict, but before matters came to a head Innocent died on Sept. 24, 1143.

(T. Cr.; C. H. Le.)

Innocent III (Lothair of Segni) (d. 1216), pope from 1198 to 1216, was born in 1160 or 1161 in Gavignano, a castle belonging to his father, Trasimund of Segni, in the Roman Campagna. Through his mother, Claricia Scotti, he was related to many noble Roman families. As a young man Lothair studied theology in Paris and canon law in Bologna under the great canonist Huguccio of Pisa, whose relatively moderate doctrines on the relationship between the spiritual and the temporal authorities lastingly influenced the future pope. In 1189 Pope Clement III, possibly a relative of Lothair, raised the young subdeacon to the dignity of cardinal deacon of St. Sergius and St. Bacchus. During the pontificate of Celestine III, Lothair did not take any prominent part in the government of the church and had time to write several theological works; two of them, "On the Miserable Condition of Man" and "On the Mysteries of the Mass," are significant expressions of the ascetic-liturgical inspiration by which this pope who was so active politically was animated.

On the very day of Celestine III's death, Jan. 8, 1198, Lothair was unanimously elected pope after only two ballots; he was ordained priest on Feb. 21, and on the next day was consecrated as bishop of Rome.

During Innocent's pontificate, in 1215, occurred the fourth Lateran council, which constituted the culmination not only of his pontificate but of the whole medieval papacy, with regard to brilliant attendance and representation of the whole church and, above all, as regards the importance of its decrees. It promulgated, for instance, the dogma of transubstantiation, bound every Catholic to confession at least once a year and communion at Easter time, forbade clerical participation in ordeals and other "judgments of God," and enacted important reforms of clergy and laity without which the medieval church would hardly have withstood internal and external dangers for another 300 years.

Innocent III's very exalted conception of the role of the papacy in the Christian world and his success in making this conception a reality would have been unthinkable without the preparations of the Hildebrandian age (*see* Gregory: *St. Gregory VII*) and without the intellectual and political developments of the 12th century. Innocent III was the fortunate heir and fulfiller where Gregory VII had been the embattled prophet and pioneer. Innocent's sermons on the day and on the anniversaries of his coronation, as well as the vast corpus of his official letters, blended the legal and philosophical-theological thought of the scholastic age with new expressions of mystical fervour and created a language and ideology of unprecedented splendour and majesty for the glorification of the papal office. At the same time the political constellations within Christendom during his pontificate allowed the pope to exercise his spiritual authority not only in the inner precincts of the church but also in all vital political questions of the day. Yet he explicitly disclaimed the right and the intention to intervene in temporal affairs as such, with the exception of course of the Papal States and of those kingdoms which had voluntarily recognized the feudal suzerainty of the papacy. As far as Germany was concerned, Innocent felt that he had very special rights, since the king of Germany was also the emperor of the Holy Roman empire and, as such, was meant to be the protector of the Roman and universal church. Because the special position of the German king-emperor *ipso facto* affected the pope's spiritual realm, Innocent believed he had the right to approve or reject dubious elections to the German throne and acted accordingly in the contest over the succession to Henry VI. Otherwise he was careful to limit his intervention in temporal matters (outside the Papal States and the vassal kingdoms) to cases in which political actions had either infringed upon spiritual rights or raised serious moral questions. Nevertheless, the combined authority claimed by the pope on these various grounds was very great indeed, and he himself often spoke of the pope's *plenitudo potestatis* (a term which goes back to Leo the Great), though he considered this always as rooted in a *spiritual* power, the power given to Peter by Christ of binding and loosing souls. Papal plenitude of power was for him essentially spiritual sovereignty, however much it could branch out into the temporal sphere for spiritual reasons. It is this claim, not a claim to temporal world rulership, which stands behind some of Innocent's most striking assertions of papal supremacy. They are properly understood, in the whole context of his reign, only as assertions of the ultimate competency of the supreme spiritual authority in any matter whatsoever by which the spiritual concerns of the church (that is to say, faith and morals) are affected.

At the beginning of his reign Innocent III was confronted with three problems: the insecurity of papal sovereignty in the Papal States; the double election in Germany; and the French-English or, to be more exact, the Capetian-Angevin war. At the time of his accession, Rome was practically independent of papal government, but Innocent soon succeeded in reasserting papal rights there. Within a few years, though not without a struggle, he had pacified the rival aristocratic factions and won over most of the people. Moreover, he had been very successful in his policy of recuperation of the Papal States with regard not only to the re-establishment of effective papal government in the so-called patrimony of St. Peter, but also with regard to the acquisition of the duchy of Spoleto, the march of Ancona, etc., which he claimed on the strength of the heretofore never fulfilled promises of Pepin and Charlemagne. For Innocent, as for the popes of the 12th century, the existence of strong Papal States in the centre of Italy was a vital prerequisite for the independence of the papacy from secular power, and doubly so after the experiences of the last decade, when the union of the Holy Roman empire with the Sicilian kingdom under Henry VI had nearly paralyzed the papacy's freedom of action.

The problem of Italy also governed Innocent's policy in the German crisis, when the princes of the Holy Roman empire, ignoring the claims of Henry VI's son Frederick II (*q.v.*), had split over the election of a new German king. One party elected the brother of the deceased emperor, Philip of Hohenstaufen, duke of Swabia; the other elected the duke of Brunswick (son of the great Guelph Henry the Lion and nephew of the English kings Richard the Lion Hearted and John), who was to be known as Otto IV. Innocent, fearing the Hohenstaufen tradition, favoured Otto, and the initial actions of Philip and his followers were not calculated to allay his fears; Frederick he hoped to restrict to his Sicilian inheritance and thus to avoid a reunion of the empire with Sicily. Philip, however, was so successful against Otto that Innocent after a few years found it necessary to resume negotiations with him, which might have led to his recognition and to the resignation of Otto or even to the pope's rejection of the latter, since he already had misgivings about him. Yet Philip unexpectedly disappeared from the scene: he was murdered in 1208 by Otto of Wittelsbach, who had a private grievance against him. Otto IV was then crowned emperor by Innocent III.

In a surprisingly short time Otto managed to alienate the pope by his blatant pursuit of plans and actions hostile to papal sovereignty in the Papal States and aiming at the reunion of the empire and Sicily. Innocent excommunicated him after he had embarked, in a flagrant breach of his promises, on the conquest of the Sicilian kingdom, and turned to the only other possible candidate for the German and imperial crowns, the young Frederick of Sicily. The pope had in fact no other choice; he also could hope that he would be able to prevail upon Frederick to keep Germany and Sicily permanently separate. A promise to that effect was no doubt a condition of his support in the German election of 1212, and in 1216 Frederick II, as king of Germany, solemnly promised to transfer full rule over Sicily to his infant son Henry. Meanwhile, Frederick, with the help of King Philip II Augustus of France, had triumphed over Otto IV and over Otto's uncle and ally, King John of England, at the battle of Bouvines (1214). Innocent, who previ-

ously had tried to end the war between France and England and had temporarily succeeded in doing so, had at this crucial moment been unable to prevent the fusion of the German throne contest with the French-English (Capetian-Angevin) dynastic conflict. (*See* also FREDERICK II [Holy Roman emperor]; OTTO IV; PHILIP [German king].)

His relationship to both western kings was very complex also in other respects. Philip Augustus, who had at all times opposed Otto IV, the relative of his Angevin enemies, had only after a resistance of 12 years obeyed the pope's demand for reinstatement of his rightful queen, whom he had repudiated. John of England had been excommunicated by Innocent because of his refusal to recognize as archbishop of Canterbury Cardinal Stephen Langton, who had been elected by the monks of the cathedral in accordance with the pope's wishes. Not until the last moment had John submitted to the pope and, in order to forestall French invasion of England, declared England a fief of the Holy See (1213). While Innocent did in fact protect John from this latest French design, he could neither deprive his own protégé, Frederick II, of Philip Augustus' military help nor could he expect John to abandon his ally and nephew, Otto. However, when John was forced to sign Magna Carta and then complained to the pope as to his feudal overlord, Innocent annulled the charter as having been extorted without his consent. Innocent did not and could not see in Magna Carta what later ages were to see in it, an assertion of law against tyranny; he considered it, not altogether without justification, as an attempt at feudal insurrection against royal authority, which he as King John's feudal overlord could not ignore.

Of the two so-called crusades which took place during the pontificate of Innocent III, one—the fourth crusade of 1202–04—was diverted to Constantinople, chiefly to suit Venetian interests and against the will of the pope. Innocent nevertheless accepted the *fait accompli* because he mistakenly believed that the establishment of the Latin empire and patriarchate of Constantinople would bring about a lasting reunion between the Eastern and Western churches (*see* CRUSADES). The other crusade was launched against the Albigensian heretics, with Innocent's approval. The pope's decision opened an unhappy chapter in the history of the church by placing under supreme ecclesiastical leadership the repression of heresy by force. It is true that the Albigensian crusade achieved what two generations of missionaries had been unable to do: it led to the extirpation of heresy in southern France (*see* CATHARI). But the price was much bloodshed, devastation and injustice, which the pope, who never demanded the death sentence against heretics, did his best to reduce to smaller proportions, though without much success.

Innocent recognized that the successes of the Albigensian heretics had been due in part to the fact that not a few of them tried to live in evangelic and apostolic poverty. This spirit Innocent, who in his personal life was frugal, encouraged wherever he found it among the Catholic clergy and laity. In granting lay and clerical communities—such as those of the northern Italian Humiliati, the Catholic Poor of Durandus of Huesca, the Dominicans, and above all the first community of St. Francis of Assisi—permission to preach and teach, Innocent went far beyond what the popes of the 12th century had thought possible and inaugurated the Mendicant orders.

In awareness of the importance of Innocent's legislation in all fields of the church's life, the canonists began to collect and publish his decretals during his pontificate; one of these collections, the so-called *Compilatio Tertia* by Petrus Collivaccinus, received the pope's official approval. A great number of Innocent III's decretals were later to enter the second part of the *Corpus Juris Canonici*, Gregory IX's *Liber Decretalium*, or *Liber Extra* (*see* CANON LAW). The far-reaching centralization of church government is reflected by Innocent's legislation in general and also by his unlimited claim to fill all vacancies of ecclesiastical offices. The great majority of these provisions, however, were used by Innocent III to support the numerous poor clerics who had been ordained by the bishops but were not adequately or not at all supported by them, the rather unhappy stratum of *clerici vagantes* well known from the history of literature. Innocent was not successful in his attempt to induce the prelates assembled at the fourth Lateran council to secure once and for all the support of the Roman Curia by the reservation of a part of their revenues; the plan, if successful, might have prevented the piecemeal fiscalism of his successors which was to do so much harm to the papacy's reputation.

In the midst of vast preparations for a new crusade which he hoped would liberate the holy land, Innocent III died suddenly, in Perugia, on July 16, 1216, from one of his frequent attacks of fever, almost certainly malaria. It is hardly possible to refrain from surmising that, had he lived longer, the fifth crusade would have had a less unfortunate end (*see* CRUSADES); also that the all-out struggle between Frederick II and the papacy might have been prevented. No other pope of the 13th century possessed the exceptional blend of strength and profound humaneness that the contemporary sources show Innocent III to have had. For portrait *see* article PAPACY.

INNOCENT III (Lando of Sezza), antipope from 1179 to 1180. The election of this schismatic cardinal on Sept. 29, 1179, constituted a purely local last flare-up of the opposition against Pope Alexander III (*q.v.*). After his protector, a member of the family of the counts of Palombara, had given him up, in Jan. 1180, he was relegated to the south Italian monastery of La Cava.

INNOCENT IV (Sinibaldo Fieschi) (*c.* 1190–1254), pope from 1243 to 1254, was born in Genoa. His family, the house of the counts of Lavagna, played a great role both in Parma and in Genoa, and not a few of them had been imperial rather than papal partisans. Sinibald studied canon law at Bologna and was himself one of the most notable canonists of the age. He came to the Roman Curia under Honorius III in 1226, and by Gregory IX was made vice-chancellor of the Roman church and cardinal priest of St. Lawrence in Lucina (1227) and rector of the march of Ancona (1235). After a vacancy which had lasted almost two years, largely because the emperor Frederick II held two cardinals as prisoners, Sinibald was elected pope, succeeding Celestine IV, on June 25, 1243. He chose the name Innocent, thus no doubt indicating his intention to follow the lead of the great Innocent III. If Frederick had hoped that he would find the new pope more amenable than Gregory IX, he was soon to be disenchanted. (For the origins of and reasons for the papacy's struggle with Frederick II *see* GREGORY: *Gregory IX.*) Even those members of the pope's family who belonged to the imperial party were to change sides. After a year of fruitless negotiations and unfulfilled agreements the pope decided to secure his full freedom of action by leaving Italy, which was under imperial control. He fled to Lyons, which, though still belonging to imperial Burgundy, was so close to the border of France that for all practical purposes Innocent was under the protection of the French king St. Louis IX, as was to become apparent later, when a French army was ready to check whatever moves against Lyons Frederick II intended. On June 28, 1245, Innocent opened the first general council of Lyons, the 13th general council of the church. In it he renewed Gregory IX's sentence of excommunication against the emperor and declared him deposed. The four principal reasons given were: perjury, disturbance of peace, sacrilege and suspicion of heresy. The first two points referred to all differences between Frederick and the popes, accumulated since Honorius III and especially since Gregory IX; the third to Frederick's capture of cardinals and other prelates; the fourth to contempt of ecclesiastical sanctions and favour shown to Muslims and Muslim customs. During the remainder of his pontificate Innocent carried on relentless war against Frederick. The struggle was conducted on both sides with all means at their disposal. Circumstantial and therefore inconclusive evidence would even seem to implicate the pope in the Italian plot to assassinate Frederick (1246); if Innocent really knew and approved, his attitude may have been influenced by medieval ideas on tyrant murder and the outlawry of the excommunicated and heretics; he did consider Frederick II both a tyrant and a heretic. In Germany Innocent succeeded in bringing about the election of two successive antikings, Henry Raspe of Thuringia and William of Holland; at least in south Germany they were unable to dislodge Frederick's son Conrad IV. The real decision in the great struggle between empire and papacy was to fall in Italy and Sicily, but neither Fred-

erick II nor Conrad IV nor Innocent IV himself lived long enough to witness it. Charles of Anjou, brother of Louis IX, who was finally to replace the Hohenstaufen in the south Italian-Sicilian kingdom, was chosen to rule there by Innocent, but he did not at that time accept; neither did Richard of Cornwall, the brother of Henry III of England, whereas Henry himself accepted for his son Edmund, who, however, was never to see Sicily. Only for a short while Innocent succeeded in obtaining the submission of Manfred, Frederick II's brilliant illegitimate son, the emperor's *de facto* heir in Sicily and the regent for the *de iure* heir, Conrad IV's infant son Conradin. While Innocent was taking possession of parts of the Sicilian kingdom, a new conflict with Manfred arose. At Naples the pope received the news that the latter had refused to follow his summons, had rebelled and beaten the papal army. Innocent, already ill, died soon thereafter, to be succeeded by Alexander IV; Manfred's star remained in the ascendancy until extinguished by Charles of Anjou 12 years later.

Innocent IV had inherited large debts from Gregory IX and needed great amounts of money for his own struggle with the emperor. He thus was driven further to increase papal fiscal exactions, contributing to the growth of anticlerical nationalism. In particular, Innocent's exploitation of the system of papal provisions to benefices aroused strong complaints. He also was the first pope who practised nepotism on a large scale, thus setting a fateful precedent.

Innocent IV granted the cardinals the red hat which is still the principal symbol of their office. In the great struggle between the Mendicants and the secular clerics at the University of Paris this pope favoured the latter; in the conflict between the Conventual and the Spiritual Franciscans he favoured the former. In 1254 he issued the bull *Ordinem veterem* through which the Franciscan friars were allowed the use of money not only in case of necessity but also in cases of manifest utility, while the pope assumed the ownership of all their possessions except where the donors had reserved it. Innocent IV (as Louis IX a little later) sent missions to the Mongols, hoping to convert them, to win their support against the Muslims, and thus to save what was left of the kingdom of Jerusalem. The Franciscan John of Pian Carpini visited the court of the great khan at Karakorum in 1246, but only received the standard order of the Mongol rulers, requiring all Christian leaders to do homage to the Mongol suzerain of the world.

Innocent IV died on Dec. 7, 1254. Among all popes he is perhaps the one who formulated the most extreme claims concerning papal authority in the political order, claims which did not in their full extent become a generally accepted part of the teaching of the Catholic Church. While in many ways Innocent continued the view on church-state relations held by his predecessors and by earlier theologians and canonists, he went beyond them at least in two important matters: negatively, when he declared that power outside the church is not truly ordained by God and therefore is merely a tyranny; positively, when he asserted that the papacy is the culmination not only of sacerdotal-pontifical, but also of royal-imperial government—in other words that, by virtue of his vicarship for Christ the king, the pope "naturally and potentially" is the monarch and leader of the political (temporal) as well as of the ecclesiastical (spiritual) order. Innocent IV pronounced such views both in his commentary to Gregory IX's so-called *Liber Extra* and in his letters, including, perhaps, the encyclical *Aeger cui levia* (the authenticity of which has been doubted, not without reason).

Blessed Innocent V (Peter of Tarentaise) (*c.* 1224–1276), pope during 1276, the first Dominican pope, was born around 1224 in the village of Tarentaise in Forez, belonging to the archdiocese of Lyons. He entered the Dominican order about 1240 and in 1255 began his studies at the University of Paris, where in 1259 he obtained the degree of master in theology. The most important among his writings is his commentary to the *Sentences* of Peter Lombard. He collaborated with St. Albert the Great, St. Thomas Aquinas and other Dominicans in drawing up a rule of studies for the order. He was provincial of the French province of the Dominicans at least from 1264 to 1267 and again from 1269 to 1272, when he was made archbishop of Lyons by Gregory X, who about a year later raised him to the dignity of cardinal bishop of Ostia. He was elected pope on Jan. 21, 1276. During his short pontificate Innocent V continued the efforts of his predecessor to bring about a crusade, to strengthen the union with the Greeks and to pacify Italy. It seems, however, that like the other French popes of the second half of the 13th century he was willing to make far-reaching concessions to Charles of Anjou. He died on June 22, 1276, and his feast is kept on the anniversary. (G. B. L.)

Innocent VI (Étienne Aubert) (d. 1362), pope from 1352 to 1362, was born at Monts in Limousin. He became professor of civil law at Toulouse and subsequently chief judge of the city. Having taken orders, he was raised in 1338 to the see of Noyon and translated in 1340 to Clermont. He was made cardinal priest of SS. Giovanni e Paolo in 1342 and cardinal bishop of Ostia and Velletri, grand penitentiary and administrator of the bishopric of Avignon ten years later. He was elected pope on Dec. 18, 1352.

As pope, Innocent revoked the reservations and commendations of his predecessor Clement VI and prohibited pluralities, urged upon the higher clergy the duty of residence in their sees, and diminished the luxury of the papal court. Largely through the influence of Petrarch, whom he called to Avignon, he released Cola di Rienzo, who had been sent a prisoner in Aug. 1352 from Prague to Avignon, and used the latter to assist Cardinal Albornoz, vicar-general of the States of the Church, in tranquilizing Italy and restoring the papal power at Rome.

Innocent established good relations with the German king Charles IV, whom he caused to be crowned emperor at Rome in 1355. The following year Charles published the famous Golden Bull (*q.v.*), which prescribed a method for the election of the German kings and passed over in silence the claims of the papacy to approve the election. Contrary to statements sometimes made, Innocent raised no objection to the bull. He had other matters in hand. In 1360 he arranged the treaty of Brétigny between France and England, a success which redounded on his head, for the peace released roving armies of mercenaries. One of these "free companies" occupied Pont-Saint-Esprit and threatened Avignon. In the end Innocent was constrained to buy them off. In the last years of his pontificate he was busied with preparations for a crusade and with negotiations for the reunion of Christendom. He died Sept. 12, 1362.

Innocent VII (Cosimo Gentile de' Migliorati) (1336–1406), pope from 1404 to 1406, was born at Sulmona. He was made papal vice-chamberlain and archbishop of Ravenna by Urban VI and cardinal priest of Sta. Croce in Gerusalemme, bishop of Bologna and papal legate to England by Boniface IX. He was unanimously chosen to succeed Boniface on Oct. 17, 1404. The election was opposed at Rome by a considerable party but peace was maintained by the aid of Ladislas of Naples, in return for which Innocent agreed not to come to terms with the antipope Benedict XIII, except on condition that he should recognize the claims of Ladislas to Naples. Innocent issued at the close of 1404 a summons for a general council to heal the schism, but the council never assembled, as the Romans rose in arms to secure an extension of their liberties and finally, maddened by the murder of some of their leaders by the pope's nephew Ludovico de' Migliorati, compelled Innocent to take refuge at Viterbo (Aug. 6, 1405). Later, recognizing the pope's innocence of the outrage, they made their submission to him in Jan. 1406. He returned to Rome in March, and, by a bull of Sept. 1, restored the city's decayed university. He died on Nov. 6, 1406.

Innocent VIII (Giovanni Battista Cibò) (1432–1492), pope from 1484 to 1492, successor of Sixtus IV, was born at Genoa, the son of Arano Cibò, who under Calixtus III had been a senator of Rome. Through the favour of Cardinal Calandrini, half-brother of Nicholas V, he obtained from Paul II the bishopric of Savona. Sixtus IV translated him to the see of Molfetta and created him cardinal priest of Sta. Balbina in 1473 and of Sta. Cecilia subsequently.

Innocent VIII was not a successful pope. His summons to a crusade against Islam went unheard, and he ended by making a treaty with the sultan Bayezid II (1489), agreeing, in return for an annual payment of 40,000 ducats and the gift of the Holy Lance,

to detain the sultan's fugitive brother Jem in confinement in the Vatican. Innocent's maneuvers in Italian politics were equally unscrupulous and unsuccessful. He deposed Ferdinand (Ferrante) king of Naples in 1489 for failure to pay arrears of tribute. But the papal arms were worsted, and Innocent had to abandon his project of incorporating Naples into the ecclesiastical state. He is remembered as the persecutor of Pico della Mirandola. The capture of Granada from the Moors (Jan. 2, 1492) gave a borrowed lustre to his pontificate. Innocent died on July 25–26, 1492. A man of lax private morals, he was a weak and unworthy pope. He left the papal camera empty and States of the Church in anarchy. (T. Cr.; C. H. Le.)

Innocent IX (Giovanni Antonio Facchinetti) (1519–1591), pope for two months during 1591, was born July 20, 1519. After taking part in the council of Trent, he became nuncio at Venice and was employed on important duties at Rome by Gregory XIII, who made him a cardinal in 1583. Under the invalid Gregory XIV he assumed almost the entire direction of affairs. He was a supporter of the Catholic League in France and of the policy of Philip II of Spain, and it was with the latter's support that he succeeded Gregory on Oct. 29, 1591. He died on Dec. 30 of the same year.

Innocent X (Gian Battista Pamphili) (1574–1655), pope from 1644 to 1655, was born in Rome on May 7, 1574. He was made auditor of the Rota by Clement VIII, nuncio at Naples by Gregory XV and legate apostolic to Spain and cardinal by Urban VIII. He was elected pope on Sept. 15, 1644, through the support of those cardinals who had opposed his predecessor Urban VIII's domestic administration and diplomatic policy, both of which he proceeded to reverse. The most emphatic and significant demonstration of this change is to be seen in Innocent's condemnation of the peace of Westphalia (1648), for which papal mediators had worked under Urban; and in the fact that practically no notice was taken of his protest by either side. In support of a pro-Habsburg policy, cardinals favoured by Spain were promoted and recognition of the independence of Portugal, then at war with Spain, was refused. In Rome, the Barberini (relatives of Urban and protégés of Cardinal Mazarin) were attacked and their property confiscated. Much of the initiative in these events was taken not by Innocent but by his sister-in-law, the notorious Olimpia Maidalchini, by whose advice he was almost completely dominated. While her diplomatic policy had the praiseworthy aim of keeping the papacy aloof from international entanglements, her greed for money led her to adopt devices which destroyed the very prestige upon which such a policy depended for its success.

In doctrine, Innocent intervened in the quarrel between the Jesuits and the Jansenists and, in the bull *Cum occasione* (1653), condemned five propositions concerning the nature of divine grace said to be in Cornelius Jansen's *Augustinus*. The quarrel thereupon entered a new phase, in which it was contended that papal infallibility did not extend to matters of fact and that the propositions were not in fact implicit in the *Augustinus*, so that the teaching of Jansen had not been condemned by the bull. On all scores, therefore, papal prestige had seriously declined by the time that Innocent died, on Jan. 7, 1655.

Blessed Innocent XI (Benedetto Odelscalchi) (1611–1689), pope from 1676 to 1689, was born on May 19, 1611, at Como, where he was educated by the Jesuits. He studied law in Rome and Naples, entered the Curia under Urban VIII and became successively protonotary, president of the apostolic chamber, governor of Macerata and commissary of Ancona. Innocent X made him a cardinal (1645), legate to Ferrara and, in 1650, bishop of Novara. He was elected pope on Sept. 21, 1676, against the opposition of Louis XIV of France. On grounds of moral character he was the outstanding pope of the 17th century, being entirely free from nepotism and invariably refusing to diverge for reasons of expediency from the policy that he considered right. He averted bankruptcy by abolishing sinecures and introducing economies. As a result he was able to finance the war against the Turks and, in particular, to subsidize John Sobieski (King John III of Poland) and the emperor in the campaign which led to the relief of Vienna in 1683.

Innocent XI had to face, in Louis XIV, a man with entirely opposite principles. Their quarrel began when two French bishops resisted an edict of 1673 which extended the *régale* (*i.e.*, the king's right to administer both the temporalities and the spiritualities of vacant sees). Innocent upheld their objection, refused the offer of a compromise and, when Louis replied by having a French synod issue the famous declaration of Gallican liberties (*see* Gallicanism) in 1682, refused to confirm the promotion of any of the clergy who had taken part in it.

The deadlock that resulted was made worse in 1687, when Innocent took action against the abuse of ambassadorial privileges by the French representative in Rome. Something approaching a schism threatened, and the deadlock was still unresolved when Innocent died. In addition, Innocent opposed Louis's candidate for the archbishopric and electorate of Cologne (1688) and would not help his plans for James II of England.

In doctrinal matters, Innocent had some sympathy with the Jansenists. On the occasion of an appeal to him by the Jesuit Thyrsus González, whose rigorist theories were being suppressed by his superiors, Innocent showed his disapproval of the lax probabilism taught by many Jesuit casuists (1680); and in 1687 he had González made general of the Jesuits. On the other hand, he was personally favourable to the Quietist Miguel de Molinos, most of whose propositions he condemned in 1687.

Any general appreciation of Innocent XI's pontificate must take into account the problems created by the ambitions of Louis XIV at a time when the church was passing through a period of doctrinal discord. Innocent's greatest contribution was perhaps his domestic reform, both moral and administrative. His integrity was unquestioned. He died on Aug. 12, 1689, and was beatified by Pius XII on Oct. 7, 1956. For portrait *see* article Papacy.

Innocent XII (Antonio Pignatelli) (1615–1700), pope from 1691 to 1700, was born in Neapolitan territory on March 13, 1615. He was educated at the Jesuit college in Rome, entered upon his official career at the age of 20, and became successively vice-legate of Urbino, governor of Viterbo and nuncio to Tuscany, to Poland and to Austria. He was made cardinal in 1681 by Innocent XI, whose pontificate he took as a model for his own, which began on July 12, 1691. Nepotism was officially condemned in a bull of 1692 and justice was administered in the papal states without regard for the status of the persons involved. The deadlock with France was broken in 1693 when both the French bishops of the synod of 1682 and Louis himself wrote letters disavowing the declaration of Gallican liberties of 1682, and Innocent agreed to the extension of the *régale* enacted in 1673 (*see* above, *Innocent XI*). Typically, Louis first assured himself that his repudiation was invalid, since a letter could not annul an edict registered by the *parlement*. In doctrinal matters, Innocent allowed the uneasy peace between Jansenists and Jesuits to continue; condemned the archbishop Fénelon's *Maximes des saints* at Louis XIV's instigation in 1699; but refused to condemn Celestino Sfondrati's book on predestination, which J. B. Bossuet had denounced as Quietistic in 1697 but which was still "under consideration" when Innocent died, on Sept. 27, 1700.

Innocent XIII (Michelangiolo Conti) (1655–1724), pope from 1721 to 1724, the son of the duke of Poli, and a member of a family that had produced several popes, among them Innocent III, was born at Poli on May 13, 1655. He served as nuncio in Switzerland and Portugal and was made cardinal and bishop of Osimo and Viterbo by Clement XI. He was elected pope, after a long conclave, on May 8, 1721, as a result of the exclusion by the emperor of the candidature of Cardinal Fabrizio Paolucci. One of his first acts was to invest the emperor Charles VI with Naples (1722); he protested in vain against the imperial investiture of Don Carlos with Parma and Piacenza. He recognized the Stewart pretender "James III" and promised him subsidies conditional upon the re-establishment of Roman Catholicism in England. Moved by deep-seated distrust of the Jesuits and by their continued practice of "accommodation" (whereby missionaries might modify Christian usage to attract converts) despite Clement XI's express prohibition, Innocent forbade their society to receive new members in China and was said to have meditated its suppression. This encouraged the French Jansenist bishops to press for the revoca-

tion of the bull *Unigenitus;* but the pope commanded its unreserved acceptance. Innocent died on March 7, 1724.

INNOCENTS' DAY (CHILDERMAS, or FEAST OF THE HOLY INNOCENTS), a festival celebrated in the Latin Church on Dec. 28 and in the Greek Church on Dec. 29 (O.S.) in memory of the massacre of the children by Herod in his attempt to destroy the infant Jesus (Matt. ii, 16–18). The church early regarded these little ones as the first martyrs. It is uncertain when the day was first kept as a saint's day. At first it seems to have been absorbed into the celebration of the Epiphany, but by the 5th century it was kept as a separate festival. In Rome it was a day of fasting and mourning.

The boy bishop (*q.v.*), whose tenure of office lasted till Childermas, had his last exercise of authority then, the day being one of the series of days which were known as the Feast of Fools (*q.v.*). Parents temporarily abdicated authority, and in convents and monasteries the youngest nun and monk were for the 24 hours allowed to masquerade as abbess and abbot. These mockeries of religion were condemned by the Council of Basel (1431). In medieval England the children were reminded of the mournfulness of the day by being whipped in bed on Innocents' morning; this custom survived to the 17th century. The day is still observed as a feast day and day of merrymaking for children in Roman Catholic countries, and particularly as an occasion for practical joking.

IN NOMINE, an English instrumental form of the 16th and 17th centuries which used the plainsong of the antiphon *Gloria tibi trinitas* (Vespers of Trinity Sunday) as a *cantus firmus* (*q.v.*) or basic melody. The *In nomine* owes its name to an instrumental arrangement of the section *in nomine Domini* of the Benedictus of the Mass *Gloria tibi trinitas* by John Taverner (*c.* 1495–1548?) which, in the mid-16th century, began to serve as a model for numerous new compositions. Although the instrumental styles changed, the title and *cantus firmus* remained the same through the Elizabethan and Jacobean periods and continued in use until the time of Henry Purcell.

(B. Tr.)

INNS AND INNKEEPERS: *see* HOTELS AND RESTAURANTS, LAWS CONCERNING.

INNSBRUCK, the capital of the Austrian province of Tirol, lies at a height of 1,880 ft. in a wide valley of the Inn river. It is built on and around the triangle formed by the mouth of the Inn's right-bank tributary, the Sill, which comes from the Brennersee. Its population ([1961] 100,695) is German-speaking and mostly Roman Catholic.

Surrounded by lofty mountains, it occupies a strategically and commercially important site at the junction of the road and railway from Germany to Italy over the Brenner pass with the thoroughfare from western Europe (Switzerland) to eastern Europe, via Vienna, over the Arlberg pass. The bridge (*bruck*) over the Inn which originally served this traffic gave the town its name and its coat of arms. The streets of this picturesque old town are narrow and there are many houses with bay windows and frescoes, some of which date from the 14th century. The main street of the old town, the Herzog-Friedrich-Strasse, is lined with 15th-century arcades; one of its most famous buildings is the old Fürstenburg adorned by the Goldenes Dachl, a balcony with a "Golden Roof," claimed to have been built by the duke Frederick "of the empty pocket" (d. 1439), which was refashioned by the emperor Maximilian I in about 1500. The emperor (d. 1519) is buried at Wiener Neustadt, but his monumental tomb is in the Franciscan or Court church (Hofkirche) which was built (1553–63) for that purpose. The church also contains the tombs of the Tirolean hero Andreas Hofer (*q.v.*) and of other heroes of the war of liberation of 1809.

The university was founded by the emperor Leopold I in 1672 and has four faculties—divinity, law, medicine and philosophy. Its great library dates from 1745, a gift of the empress Maria Theresa. Innsbruck has four museums: the Ferdinandeum, with prehistoric, industrial art and natural history collections and a picture gallery; the museum of Tirolean folk art; the Regimental museum of the Imperial rifles, on the Berg Isel, with exhibits of historical military interest; and in the castle of Ambras, where are parts of the collections of Archduke Ferdinand II of Tirol. Innsbruck is one of the most popular tourist and health centres in central Europe. It is easily accessible by road, rail and plane (alpine airport).

Originally a small market centre belonging to the Bavarian counts of Andechs, it developed into a prosperous town because of its strategic position. It was surrounded by walls and was given a mint, and in 1239 it received its own rights and privileges. The duke Frederick, who is supposed to have built the original "Golden Roof" onto the front of his residence in about 1420, made Innsbruck the new capital of Tirol in place of Merano. In 1460 his son, the duke Sigmund, transferred his residence to Innsbruck.

From 1363 to 1918 Innsbruck and the Tirol belonged to the house of Habsburg. The town became a battlefield in the war of liberation when four battles were fought on Berg Isel under the leadership of Hofer after Napoleon had given Innsbruck to the kingdom of Bavaria in 1806. With the rest of Austria it was annexed to Germany in 1938 and was damaged in air raids during World War II; in 1945 it was first occupied by U.S. troops and became later the headquarters of the French zone of occupation.

INNS OF COURT AND CHANCERY. The four inns of court seated in London—Lincoln's inn, Gray's inn, the Inner Temple and the Middle Temple—have frequently been referred to as "colleges in a university of law," and in their general structure, system of government and functions this analogy holds good. In Coke's *Reports* they are described as "the most famous Universitie for profession of law only," and they are referred to by Fortescue, Coke and Selden as universities for the study of the law on the same footing as the universities of Oxford and Cambridge. Just as the universities are responsible for the preparation of students for a degree and for their discipline, so the inns of court are responsible for the education and discipline of their students; and their respective governing bodies, the benches, exercise the exclusive right of admitting persons to practise by a formal call to the bar.

They are voluntary societies, unchartered, unincorporated and unendowed. Hence their early history is very obscure and the date of their respective foundations cannot be precisely determined, for they did not own land but only leased it, and records of such transactions are much more difficult to trace than dealings with a fee simple. Since the inns were not endowed by any benefactor, there was no foundation charter, and no statutes, to be preciously preserved.

Since the inns were primarily concerned in the middle ages with legal education, attempts have been made to connect them with the early educational establishments of London. No doubt the city was well furnished with schools where the rudiments of Latin, grammar, logic, etc., were taught, possibly with those odd tags of law which often appeared as illustrative material in the course of rhetoric. But this is not sufficient to account for the rise of the inns of court, which were devoted to the technical study of English, not Roman, law and which seem to have been concerned from the first with students well beyond the schoolboy stage.

There is nothing to suggest that while the common law was still young, its administrators had any systematic education in English law; it was learned in the course of service, the first rudiments possibly as private clerk to some official. These conditions persisted well into the 13th century. By about 1256 Henry de Bracton's massive book on the laws and customs of England and the bulk of the plea rolls both show that the common law was extensive and intricate, conducted by numerous skilled men in courts which had considerable establishments.

This law had little in common with Roman and canon law; whence it followed that there was no question of the universities teaching English law. Moreover, there arose a class of men, literate but lay, who took an interest in law. They dominated, and created, the legal profession, and faced and solved the problem of English legal education. The inns of court were the answer they supplied.

This emergence of the literate layman is clear from the appearance (contemporary with Bracton's last years) of treatises on English law in French instead of Latin. From them and other sources it seems clear that already English law was being taught. Many were studying—the surviving manuscripts of these manuals are numerous—and the teachers were able enough to write quite good little books.

The students listened to arguments in court, and discussed law among themselves. That does not mean that there was any permanent inn; the students may well have made their own private arrangements both for teaching and lodging.

The general educational history of the city of London does not seem to show any genuine relevance to all this. It is usual to mention the writ of 1234 whereby Henry III ordered that "no regent of law schools in the said city shall teach laws (*leges*) there henceforth." This language suggests teaching of academic standards, and *leges* without further qualification must mean Roman law. F. W. Maitland's suggestion that the schools in question were perhaps the schools of St. Paul's cathedral is attractive, were it not for the fact that one would not expect the civic authorities to exercise jurisdiction over them.

Whatever its meaning, the writ of 1234 cannot be taken as having anything to do with the teaching of English law, whether at inns of court or elsewhere.

By about 1260 laymen were taking up law studies, and didactic manuals were written in the vernacular French for them; law students attended arguments in court and discussed points of law among themselves, from which it is a fair inference that the students not only met in court but almost certainly congregated out of court.

It could be assumed that the students were well-to-do—in 1305 the chief justice suspected that a knotty case before him had been manufactured by some apprentice who bought the land in order to see how it would fare in court. Finally, by about 1300, lawyers of various sorts were numerous and needed regulation. The city made orders for practitioners before the London courts in 1280, and in 1292 the king commanded his judges to select from different counties 140 apprentices and attorneys and to allow no other to meddle with legal business.

Bearing all this in mind, it is a natural inference that law students should have acted like university students elsewhere, hiring hostels or inns where they could live together. It might even be an established practitioner who leased a house, taking in students and guiding their studies. This system was common in English and foreign universities among such men as could afford to live on such a scale. To assist the poor university student, benefactors often founded colleges (or conferred endowments upon some existing inn or hall) to enable poor scholars to stay. This did not happen in London; law students had the means (sometimes borrowed) to keep themselves at an inn without the aid of collegiate endowments. It is not surprising that the inns were at first liable to move as leases expired or more suitable premises were found, and in time leases would be given (or renewed) for long terms; in the Tudor period the growth of the trust enabled the inns to acquire the ownership of their quarters.

Aspirants to practice in the superior courts were only a small proportion of all those needing a legal education. There was a keen demand for stewards and legal advisers to landowners everywhere, conducting general business and keeping manorial courts. These men needed the rudiments, but not the refinements, of the common law, and they too came from the class of literate laymen. There was likewise the large class of attorneys, and a growing class of bookkeepers and correspondence clerks. Some part of their knowledge could be got from *dictatores*, professional teachers of letter writing; more still by joining an inn of chancery.

Chancery clerks (being then clergy in at least minor orders) had long lived as part of the household of the chancellor, but in the 14th century they had become too numerous, and the household broke up as groups of clerks either combined to take inns or married. Many seem to have taken in students for training and, since the penning of writs and other legal documents was a prominent part of their work, a good grounding in law could be obtained in an inn of chancery. By the end of the 14th century these inns were in danger of being submerged by a flood of attorneys-to-be and of students who used a stage at an inn of chancery as a preparation for entering an inn of court. Eventually each inn of court secured control of one or more inns of chancery and supervised its affairs, appointed readers to teach in it and later often bought its premises, thus becoming its landlord.

By the beginning of the 15th century the four inns of court were established bodies with tradition behind them. They were governed by their benchers, who had previously given at least two courses of lectures (readings), and who presided over mock arguments (moots) in which students argued before them difficult

points of law. The standard was high and the teaching thorough. A number of manuscript reports of readings and moots survive.

Since the law was highly technical, proficiency could only be acquired by following the severe studies of the inns, so that in practice the inns had a *de facto* monopoly. This soon became recognized, and when benchers called certain students to the bar of their inn, those students were regarded as qualified apprentices or barristers. The inns steadily remained organizations of students. When the crown conferred the degree of serjeant-at-law upon a few outstanding barristers, they at last ceased to be apprentices and withdrew from their inn to the Serjeants' inn. The judges were always serjeants and so remained in Serjeants' inn. In spite of the severity of their studies, there were in the 15th and 16th centuries many students of the inns who had no legal ambitions but joined them for the purpose of general education (which was by no means neglected there). Since the universities were still strongly ecclesiastical, the inns were much frequented by the sons of wealthy families who had no intention of becoming lawyers.

By the end of the 16th century the inns of court began to exclude attorneys and solicitors and refused to call them to the bar, with the result that attorneys especially fell back upon the inns of chancery, and were finally in a profession distinct from that of the barristers.

The golden age of the inns of court may well have been from the middle of the 15th century (as Sir John Fortescue described it) to the early years of the 16th century. The inns (by the end of that period) had acquired the freehold of their sites and began the building of splendid halls which continued through the reign of Elizabeth I. Their material prosperity was also shown by their magnificent feasts and the entertainment offered to the sovereigns. If a man left an inn to become a serjeant, feasting on the scale of a coronation was expected. The system of legal education was at its best and most vigorous during that period.

Various causes brought about its decline. The great activity of the printing press led students to suppose that they could learn more quickly and more easily from printed books, and so they neglected attendance at readings and moots. Indeed, students performed moots by deputy. If students were reluctant, so were the readers, who were unpaid and lost much time from their practices in preparing and delivering readings, and latterly had to provide very costly feasts; many paid heavy fines to escape the office. The judges, who had assumed vague powers of giving directions to the inns, often tried to compel observance of the old system, but it was clearly on the decline. It broke down completely during the Civil War, and the desperate efforts at the Restoration to revive it were abandoned. Readings ceased in 1677. Only the fees survived, and having paid them, the student was deemed to have fulfilled all his duties.

During the 18th century the cessation of the old system left a void which was slowly filled by new arrangements. There had been no readers to recommend students for call to the bar since 1677, so the four inns finally agreed (in 1762) to call students who had kept a stated number of terms; later it was settled that eating three dinners was equivalent to keeping the whole term. The benchers kept their position as the sole governing body of each inn and stoutly resisted the claim that king's counsel should become benchers as of right. It was also settled that the head of the inn was the bencher holding the office of treasurer, which passed by rotation in order of seniority. Since the Judicature acts of 1873, 1874 and 1875 the grade of serjeant-at-law has been extinct, with the result that judges, no longer being serjeants, can remain members of their inns and in fact are benchers.

The inns of chancery were not fitted to become the professional organ of so large a body as the attorneys and solicitors, if only because these practitioners were not congregated in London. They therefore created their own society, and the inns of chancery one by one were sold.

The common law commissioners of 1854 investigated the inns of court, and, thus stimulated, the inns took steps to resume their educational functions. Readerships were established and eminent lawyers engaged in teaching with a view to examinations conducted by the Council of Legal Education, representing all four inns.

Lincoln's Inn.—The legends connecting this inn with Henry de Lacy, earl of Lincoln (d. 1311), and with John Thavie the armourer (d. 1348) have no historical foundation and rest on misunderstandings. It is certain that Lincoln's inn was lessee of the bishops of Chichester on land west of Chancery lane by 1422. It was also shown by G. J. Turner and E. Williams that it once occupied land on the east side of the same lane which had been accumulated between 1331 and 1348 by Thomas de Lincoln, king's serjeant. It is presumably there that Lincoln's inn first came into existence, being known, as often, by the name of the landlord whose "inn" the lawyers rented.

By 1369 Thomas de Lincoln had conveyed the whole of the freehold to the abbey of Malmesbury. It does not follow that the lawyers were already in possession by 1369, for the house may still have been called by Lincoln's name even after he had disposed of it. But it is quite certain that in 1399 the abbey was receiving rent for "the new inn at London called Lincoln's inn." The bishops of Chichester ceased to reside at their house on the other side of Chancery lane in 1412, and evidently the inn moved across the street between 1412 and 1422 to the present site.

The earliest records of Lincoln's inn, the *Black Books*, commence in 1422. The control of the society was vested in the council, which consisted of the masters of the bench. Next in rank came the utter-barristers, those who had been called to the bar, and the inner-barristers or students, so called because at the moots held in the hall of the inn the former sat on the outermost part of the form which represented the bar of the court and the latter sat inside and between them. Formerly attorneys and solicitors also might be members of the inn. It is interesting to note that Sir Thomas More's grandfather was chief butler prior to his call in 1470. The chief butler at this period acted rather as clerk to the council than as butler in the modern sense. He was clearly an educated man. The bishop of Chichester's palace and the chapels of Our Lady and of St. Richard sufficed for the needs of the society for nearly a century. The Bishop's hall was pulled down in 1491 and the present Old hall erected in its place in 1506. When this proved insufficient for the growing membership the present New hall was built in 1843. The present chapel, constructed by Inigo Jones, was completed in 1623. Thavie's inn (which had no connection with the armourer) has existed since 1376 as an inn of chancery, and its site was acquired by Lincoln's inn in 1550. It was sold by the benchers in 1769 and thus erased as a legal institution. The other inn of chancery attached to Lincoln's inn, Furnival's inn, dates from about 1406. Its ancient hall, in Holborn, still exists.

Gray's Inn.—The site of Gray's inn formed part of the manor of Portpoole, which passed in 1294 to the dean and chapter of St. Paul's, who let it to Reginald de Grey, chief justice of Chester and first Lord Grey of Wilton. There is little doubt that the judge lived there with his clerks and other officers of his court and law students. The Greys had for a century been connected as officials with both the court of exchequer and the chancery. Gray's inn continued in the de Grey family till the conveyance of the manor of Portpoole in 1503 to the prior and convent of the charterhouse at Sheen, from whom the benchers held the inn until the dissolution of the monasteries in 1539 when the rent became due to the crown. In 1733 the benchers acquired the freehold. The existing records of the inn only commence with the year 1569, but Chief Justice Sir Thomas Billing told William Paston in 1454 that he had been a fellow in Gray's inn; that would imply that the inn was in existence about 30 years earlier. The constitution and officers of the inn are similar to those of the other inns. When the records open, governors had ceased to be elected. The control of the inn was vested in the masters of the bench. The office of pensioner was abolished in 1630, but the name survives in the *Pension Book of Gray's Inn* and in the old and new pension chambers, where the masters of the bench meet for the discussion and transaction of the business of the society and for relaxation. Of the servants of the inn the chief were in 1570 the steward, the master butler, the priest and the master cook. Whether anything of the old hall of the de Greys remains cannot be determined. It was rebuilt or re-edified under the supervision of Nicholas Bacon and Gilbert

Gerard in 1556. It was a particularly fine specimen of Tudor architecture and may be compared with the Middle Temple hall, which it much resembled, although on a smaller scale. In 1941 the hall and much else perished in an air raid, but the screen and heraldic glass had been removed to safety. The oak screen is said to have been presented by Elizabeth I. The chapel was reconstructed or re-edified in 1615 and finally restored in 1893. The library is first mentioned in 1555.

The inns of chancery affiliated to Gray's inn were Staple inn and Barnard's inn. The former was an inn of chancery in the reign of Henry V and later became the property of the Actuaries society. Barnard's inn, named after Lionel Barnard who leased it from the dean of Lincoln, became an inn of chancery at least before 1451. The inn was later the property of the Mercer's company.

The Inner and Middle Temples.—As far as the history of the Inner and Outer Temples can be traced, they have always been separate societies. Writing about 1387, Geoffrey Chaucer describes the "Manciple of a Temple" who had 30 lawyers as his masters, which suggests something like an inn, perhaps more than one, as already existing. The Temple had been the seat in England of the Knights Templars, on whose suppression in 1312 it passed after an interval of some years to the Knights Hospitallers of St. John of Jerusalem. The first mention of the Middle Temple as a distinct society occurs in a will dated 1404, and of the Temple as an inn of court in the *Paston Letters,* where, under date Nov. 1440, the Inner Temple is spoken of as a college, as is also subsequently the Middle Temple. The two societies continued as tenants to the Knights Hospitallers of St. John until the dissolution of the order in 1539; they then became the lessees of the crown and so remained until 1609, when James I made a grant by letters patent of the premises in perpetuity to the benchers of the respective societies on a yearly payment by each of £10, a payment bought up in the reign of Charles II. In this grant the two inns are described as "the Inner and the Middle Temple or New Temple." Excepting the church and the priests' hall at the west end of the hall, nothing remained in modern times of the edifices belonging to the Knights Templars, the present buildings having been almost wholly erected since the reign of Queen Elizabeth I or since the Great Fire (1666), in which the major part of the Inner Temple perished. The Temple suffered heavy destruction by air raids during World War II. The church has been in the joint occupation of the Inner and Middle Temple from time immemorial—the former taking the southern and the latter the northern half. The round portion of the church was consecrated in 1185, the nave or choir in 1240. The largest and most complete of the four remaining round churches in England, it is built on the plan of the church of the Holy Sepulchre at Jerusalem. Narrowly escaping the ravages of the fire of 1666, this beautiful building is a perfect specimen of early Gothic architecture in England. The constitution of both societies is similar to those of the other inns, but the meetings of the benchers are in both styled a "parliament," which is further evidence of their antiquity.

The Inner Temple comprehends a hall, parliament chamber, library and other buildings often rebuilt and extended, the present buildings being completed in 1870. The library owes its existence to William Petyt, keeper of the Tower records in the time of Queen Anne, who was also a benefactor to the library of the Middle Temple. Belonging to the Inner Temple, Clifford's inn was the most important of the inns of chancery and numbered among its members Sir Edward Coke and John Selden. Clement's inn was an inn of chancery before the reign of Edward IV, taking its name from the parish church of St. Clement Danes; it was the inn of William Shakespeare's Master Shallow, and the Shepherd's inn of William Makepeace Thackeray's *Pendennis.*

The Middle Temple possesses in its hall one of the most stately of existing Elizabethan buildings. It was completed in 1572, the richly carved screen at the east end in the style of the Renaissance being erected in 1575. The hall, which was preserved unaltered and survived the air raids of World War II, has been the scene of numerous historic incidents, from the time of Queen Elizabeth I. The library, which contains about 70,000 volumes, dates from 1641. In civil, canon and international law, as also in divinity and ecclesiastical history, the library is rich; it contains also some curious works on witchcraft and demonology. There was only one inn of chancery connected with the Middle Temple, New inn, the buildings of which were razed. *See* also Doctors' Commons; Legal Profession: *England and Wales.*

The King's Inns, Dublin.—The legal school in Ireland, the King's inns, corresponds closely to the English inns of court and is in many respects in unison with them in its regulations with regard to the admission of students into the society and to the degree of barrister-at-law, as also in the scope of the examinations enforced. Formerly it was necessary to keep a number of terms at one of the inns in London—the stipulation dating as far back as 1542 (33 Henry VIII, c. 3). Down to 1866 the course of education pursued at the King's inns differed from the English inns of court in that candidates for admission to the legal profession as attorneys and solicitors carried on their studies with those studying for the higher grade of the bar in the same building under a professor specially appointed for this purpose—herein following the usage anciently prevailing in the inns of chancery in London. This arrangement was ended by the Attorneys and Solicitors act (Ireland) of 1866. The origin of the King's inns may be traced to the reign of Edward I. when a legal society designated Collett's inn was established outside the walls of the city; it was destroyed by an insurrectionary band. In the reign of Edward III, Sir Robert Preston, chief baron of the exchequer, gave up his residence in the city to the legal body, which then took the name of Preston's inn. In 1542 the land and buildings known as Preston's inn were restored to the family of the original donor, and in the same year Henry VIII granted the monastery of Friars Preachers for the use of the professors of the law in Ireland. Thenceforward the legal body was known as the King's inns.

In discipline and professional etiquette the members of the bar in Ireland differ little from their English brethren. The same style of costume is enforced, and the same gradations of rank are observed. The King's inns does not provide chambers for business purposes; there is consequently no aggregation of counsel in certain localities, as is the case in London around the inns of court.

Scotland.—The corporation known as the Faculty of Advocates in Edinburgh corresponds with the inns of court in London and the King's inns in Dublin and, like them, regulates the admission of barristers. *See* Advocates, Faculty of.

INONU, ISMET (1884–), Turkish army officer and statesman, a close colleague of Mustafa Kemal in the critical years of the Turkish republic and subsequently three times president of it, was born at Izmir (Smyrna) on Sept. 24, 1884, the son of Rashid, an eminent lawyer. Educated at the Artillery school and at the General Staff college in Istanbul, he served on the general staff of the 3rd army at Edirne. During the First Balkan

War he became major and chief of staff of the Yemen army. Promoted lieutenant colonel in World War I, he commanded the IV army corps in Syria in 1916. At the time of the Turkish surrender (Oct. 1918) he was in Istanbul, but later he joined Mustafa Kemal's National Liberation movement in central Anatolia.

When the grand national assembly was elected in Jan. 1920, Ismet became deputy for Edirne, but later he sat for Malatya. After the Greek occupation of western Anatolia (*see* GRECO-TURKISH WAR), he was appointed chief of the general staff in June 1920. Thus began a close co-operation between the cautious and stubborn Ismet and the shrewd and long-sighted Mustafa Kemal. When the Greeks advanced deep into Anatolia in July 1921, Ismet, by then a pasha, succeeded in turning the tide at the battle of Inonu, near Ankara. This was followed by the defeat of the Greeks on the Sakarya river and their expulsion from Anatolia.

Appointed foreign minister in Oct. 1922, Ismet represented Turkey at the Lausanne conference, where he strongly opposed Lord Curzon, the British foreign minister. Supported by Mustafa Kemal, he gained most of the Turkish demands in the treaty of Lausanne (July 24, 1923), though the question of the Straits was settled only by the Montreux convention in 1936. When Mustafa Kemal became president of the republic (Oct. 1923), Ismet became prime minister. He resigned on Nov. 21, 1924, but returned on March 4, 1925, and remained in power until Sept. 23, 1937. It was in 1934 that he took the surname of Inonu (commemorating his victory in 1921), while Mustafa Kemal took that of Ataturk.

When Ataturk died on Nov. 10, 1938, Inonu was elected president the following day; and he was re-elected in 1943 and 1946. All his abilities were needed during World War II to keep Turkey neutral and to maintain treaty obligations to both sides. After World War II, however, he encouraged the creation of a parliamentary opposition, and the Democratic party defeated his Republican People's party on May 14, 1950. He ceased to be president on May 22, and led the opposition. As a result of the general election of Oct. 1961, Inonu became in November prime minister for the third time. (M. P. P.)

INOUE (INOUYE) **KAORU** (1835–1915), one of the five elder Japanese statesmen of the Meiji period, was born in 1835, a samurai of the Choshu fief. He was a close friend of Itō Hirobumi, who later became Japan's first prime minister. They grew up together, studied in Choshu and in 1862 went to Edo (Tokyo) intending to help drive the foreigners out of Japan. They soon found this objective quite impractical and, wishing to study the foreigners' awesome power, they secretly left Japan in 1863 and worked their way to England as common sailors. The following year, when news reached them of the crisis over the bombardment of foreign ships by their own clan at Shimonoseki, they hurried home to urge their clansmen and the Tokugawa to seek peace. They failed in this effort and Inoue was severely beaten by reactionary samurai. Like Itō, Inoue became an ardent member of the party seeking to overthrow the shogunate, for he believed that only under the personal government of the emperor could Japan be unified and modernized. With the overthrow of the Tokugawa in 1867, Inoue became a leading member of the government, and held important positions in the ministries of finance, industry and foreign affairs during the first decade the new government was in power. After Itō became prime minister in 1885, Inoue served in succession as foreign minister, minister of the interior and minister of finance.

He retired from active politics in the late years of the century and turned his attention to business. He was closely associated in business with Shibusawa Eiichi; he became one of the pillars of the financial world and had close connections with the Mitsui bank. During the Russo-Japanese War he was named special adviser to the minister of finance and at the request of the emperor attended all important state councils. He became a marquess in 1907. Despite his retirement from active politics in 1898, he continued to have an important influence on the state of affairs behind the scenes and was until his death one of those elder statesmen (genro) to whose advice the emperor had recourse in reaching decisions on the most difficult political questions. (T. C. SH.)

INOWROCLAW, a town of Poland in the Bydgoszcz *wojewodztwo* (province), is situated in the centre of Kujavia, and is a road and rail junction. Pop. (1960) 47,000. As the former capital of Kujavia, Inowroclaw had the character of an industrial and trade town as early as the 15th century (mills, distilleries, breweries). Discovery of rich salt deposits in the mid-19th century intensified its industrial importance. The salt deposits provide one-sixth of Poland's total supplies and have also facilitated the development of Inowroclaw as a health resort.

To the south of Inowroclaw lies a group of lakes (the Goplo and others) which, with the Notec river, constitute one of Poland's most attractive waterways. (K. M. WI.)

INQUEST, a body appointed by public authority to inquire into designated matters. In the modern period the term most frequently refers to an inquiry made by a coroner to determine the cause of death. Historically, the coroner's jury is closely related to the practices that eventually developed into the grand jury, the petit jury and the jury in condemnation proceedings. Originally persons appointed to the coroner's jury were expected to inform the crown's officers of local events with which the members were assumed to be familiar. Only later was the jury conceived as a body whose function is to make a finding on the basis of evidence submitted to it at a hearing.

See CORONER; JURY. (F. A. A.)

INQUISITION, the name of a papal judicial institution that combated heresy, alchemy, witchcraft, etc., and wielded considerable power in medieval and early modern times. The Inquisition furnishes a favourite argument to those who accuse the Roman Catholic Church of tyranny and cruelty. The name is derived from the Latin verb *inquiro*, "inquire into," which emphasizes the fact that the inquisitors did not wait on complaints but sought out heretics and other offenders. Investigating offenses rather than waiting for accusations had been practised by both church and state long before any means other than moral suasion were used to secure uniformity of belief. It was only when heresy became widespread and seemed to threaten the existing order that churchmen departed from the traditional position as stated by St. Bernard of Clairvaux: "Faith must be the result of conviction and should not be imposed by force [*Fides suadenda, non imponenda*]. Heretics are to be overcome by arguments, not by arms."

Before the 12th Century.—During Christianity's first three centuries the penalties against heretics were exclusively spiritual, usually excommunication. When, however, the emperors became Christian, Arian emperors persecuted the Catholics and Catholic emperors persecuted the Arians. After Theodosius I the Great made Christianity the established religion, late in the 4th century, heretics came to be looked upon as enemies of the state and laws were enacted against them. Penalties included confiscation of property, exile, loss of civil rights, etc.; only those whose doctrines or practices threatened society (*e.g.*, the Manichees and Donatists) were subject to the death penalty. The Fathers of the Church, as a rule, were opposed to state intervention. Optatus of Milevis, however, defended the death penalty for the fanatical Circumcellions (north African peasants, attacking Catholics in the Donatist cause). Augustine at first declared himself against the application of civil penalties but later came out in favour of moderate severity. Martin of Tours and Ambrose of Milan protested the execution of Priscillian (the first heretic to receive capital punishment) in 385. St. John Chrysostom appealed to Matt. xiii, 30, "Let both [the wheat and the weeds] grow together until the harvest," to justify his rejection of temporal punishment of heresy; still he was opposed to letting heretics spread their doctrines.

During the three centuries that preceded A.D. 1000, little is heard of the coercion of religious dissidents. About 1000, however, the doctrines of the Cathari, called in France Albigenses, began to spread in Europe (*see* CATHARI). In 1022 Robert II of France had 13 heretics burned at Orléans, and the emperor Henry III had some hanged at Goslar in 1051. Throughout the 11th and early 12th centuries dissenters were occasionally executed by the civil power, but the initiative in these cases seems to have come as a rule from the people, threatening to lynch the

dissidents, rather than from either the secular or the ecclesiastical authorities.

Origins of the Medieval Inquisition.—After about 1150 opinion in regard to the employment of force to secure ecclesiastical unity began to change. The numbers of the Cathari and, somewhat later, the Waldenses (*q.v.*) had increased to such an extent that the state as well as the church appeared to be threatened. That heresy had to be repressed by force was soon taken for granted. The revival of Roman law, in which the emperor appeared as the defender of orthodoxy, led to the same conclusion. The third Lateran council (1179) passed strict decrees against heretics. In the Synod of Verona (1184) Pope Lucius III, in agreement with the emperor Frederick I Barbarossa, decreed the excommunication of heretics and their protectors; heretics who, after proper ecclesiastical trial, refused to recant and do penance, as well as those who after repenting had relapsed, were to be handed over to the civil power for punishment. The emperor for his part declared heretics under the ban of the empire.

The ecclesiastical Inquisition was at first in the hands of the local bishops, who found it difficult to cope with heresies which naturally did not respect diocesan limits. Moreover, during the 11th and 12th centuries the centralization of the church had made considerable progress. The result was that Innocent III began to send legates to preside over the repression of heresy; about 1200 he sent two Cistercian monks against the Albigenses in southern France.

The fourth Lateran council (1215) decreed that rulers who failed to rid their territories of heresy were threatened with deposition and loss of their dominions, and this led them to decree the death penalty for heresy: Aragon in 1197, Lombardy in 1224, France in 1229, Rome in 1230, the Two Sicilies in 1231 and Germany in 1232. To prevent the Inquisition being used for political purposes, however, Gregory IX reserved the apprehension and trial of heretics to the church, and instituted the papal Inquisition. He did not abolish the right of the bishops to judge heretics in their own dioceses but urged them to support the papal inquisitors. In 1233 he wrote to the bishops and prelates of France:

> When we consider that you are distracted by the tumult of your different occupations and are scarcely able to breathe because of the distressful flood of cares which submerge you, we have decided that it is only right to give part of your burden to others and accordingly to send to the kingdom of France and neighboring provinces against the heretics some Dominican friars. We enjoin that you receive them kindly and treat them with honor by giving them such good advice, aid and support in this office and in other respects that they may be able to carry out the task entrusted to them.

When in the course of time it became clear that the Inquisition did infringe upon the rights of the bishops, the Council of Vienne in 1312 prescribed co-operation between papal and episcopal inquisitors.

Papal inquisitors in medieval times were often members of the Dominican order, though Franciscans and members of other religious orders as well as secular clergy were employed at times. As the Inquisition had no courts of its own, the convent of the order to which the inquisitor belonged was normally used as a court.

Early Inquisition.—The Inquisition was concerned with deliberate, stubborn and public denial of a doctrine of the church by baptized Christians. Jews, Muslims and heathen were subject to the Inquisition only indirectly, if they tried to lead Christians into heresy or unbelief. The medieval Inquisition was concerned with the heretics of the time—the Cathari, the Waldenses, certain Béguines and Beghards, the Apostolici—most of whom, because of their antisocial tenets, would be treated harshly even by many modern governments. Protectors of heretics were by that fact suspect of heresy, as were the excommunicated who made no effort to have the excommunication lifted. Devil worship, adultery, incest, etc., were eventually included in the purview of the Inquisition.

The power of the inquisitors was great, and the office was looked upon as a high dignity. Inquisitors could name deputies and had assistants (*socii*), notaries, police and counselors. Since they could excommunicate even princes, they usually had the support of the civil power. Before being chosen for their office the inquisitors had distinguished themselves for learning and upright life. In the course of time manuals for their guidance were composed, those of Bernard Guy and Nicholas Eymeric being the best known. In the judgment of their contemporaries, most of the inquisitors performed their duties in a spirit of mercy and understanding. Some canonized saints were numbered among them, notably St. Peter Martyr (of Verona), who has been called the saint of the Inquisition. Born of Catharist parents in 1205, Peter early turned to orthodoxy and in the course of time became a Dominican friar. He distinguished himself as a preacher in Lombardy, his faith and piety winning much influence, and about 1234 he was appointed inquisitor by Gregory IX for the Milanese territories; later his jurisdiction was extended to include most of northern Italy. Peter did not hesitate to punish heretics who would not recant, but his professed desire was to convert them. His rigour and his success in bringing about conversions won him many enemies, and on April 6, 1252, he was assassinated; Pope Innocent IV canonized him the following year.

Many inquisitors, however, won reputations for excessive cruelty. Konrad (*q.v.*) von Marburg, appointed inquisitor for Germany by Gregory IX in 1231, was assassinated in 1233 and has gone down in history as the type of the heartless heresy hunter. Konrad was apparently a member of the secular clergy and had been confessor to St. Elizabeth of Hungary, whom he treated with extreme severity. He was undoubtedly rigid (with himself as with others), but his assassination was due probably as much to German dislike for the institution of the Inquisition, which was soon suppressed in Germany, as to his cruelty.

Robert le Bougre, who escaped assassination but whose reputation rivals that of Konrad, was another early inquisitor whose name was remembered with hatred. In his youth Robert is said to have renounced Catholicism for love of a Catharist girl, and he lived for years as a member of the sect. After abjuring, he became a Dominican and in 1233 was appointed by Gregory IX one of the first papal inquisitors for France, being suspended the following year on the charge of lack of moderation. Reinstated as inquisitor in 1235, he did not change his methods, and his terrorism led to his dismissal and imprisonment in 1239.

Procedure.—When the inquisitor came to a place where heretics were known or suspected to reside, he assembled the clergy and people to listen to a solemn discourse. Those guilty of heresy were urged to present themselves to the inquisitor within a stated time, called a time of grace and lasting a fortnight or a month. On those who confessed their guilt lesser sentences were imposed. Those who knew of heretics were ordered under pain of excommunication to make them known to the inquisitor. At the expiration of the time of grace, those accused or suspected were hailed before the inquisitor. If they admitted their guilt and were ready to renounce their errors, they had to do so in a solemn gathering (*sermo generalis; see* below) in which they were sentenced. Those who pleaded not guilty were questioned by the inquisitor. If the interrogation led to no decision, witnesses were introduced, the testimony of two trustworthy men being considered sufficient to convict if the suspect could not refute the charges.

The obligation to report suspects was a kind of invitation to denounce personal enemies. The accused, moreover, found it hard to defend himself, since during most of the 13th century he was not informed of the identity of his accusers. The only safeguards lay in the fact that false witnesses were punished and that the counselors of the inquisitor had to testify to the trustworthiness of those whose testimony was accepted. It was not until the time of Boniface VIII (1294–1303) that the names of accusers were revealed to the accused. Witnesses for the defense rarely appeared, since this of course might lead to their coming under suspicion. The lawyer of the accused, when he had one, was little more than a counselor, charged more with getting a confession than with defense.

The use of torture, which had been a customary judicial procedure among the Greeks and Romans, was at first rejected by the northern peoples; ordeals and oaths took its place. But when the

church outlawed ordeals and Roman law was revived, torture also was revived. In 1252 Innocent IV, by the bull *Ad extirpanda*, authorized its use by the inquisition to obtain confessions and the names of other heretics. Later Clement V decreed that it could not be used by papal inquisitors without the consent of the local bishop. According to canon law torture could be employed only once, but some inquisitors ordered it a second time as a continuation. It is difficult to determine whether or not torture was much used.

Sentence.—On admission or conviction of guilt of lesser misdeeds, the prescribed penalties included recitation of prayers, fasting, almsgiving, flogging, pilgrimages, etc. Wearing of a yellow cross, imprisonment, confiscation of property, etc., were imposed for more serious heresy. Life imprisonment was the extreme penalty the inquisitor could impose. Condemned heretics who refused to recant, as well as those who relapsed after condemnation and repentance, were turned over to the secular arm for punishment. The inquisitor had to consult his counselors (between 9 and 50 clerics and laymen) about the sentences and could not hand a prisoner over to the civil authorities without the consent of the local bishop. Every effort was put forth to induce the heretic to recant; sometimes, to this end, his delivery to the secular power was deferred for as long as a year.

The death penalty was imposed by the civil authorities and not by the church, but the ecclesiastical authorities were in fact morally responsible, because they could excommunicate a ruler who did not carry out the sentence where it was prescribed by law. In handing the heretic over to the secular power, the inquisitor asked that punishment be carried out without shedding blood or endangering life, but this was merely an antique formula intended to influence the condemned to ask for mercy and to emphasize the fact that the church did not itself shed blood. Bodies of persons condemned after death were disinterred and burned.

Life imprisonment, a not uncommon penalty, was imposed on those who confessed under torture as well as on those who recanted after being sentenced to death. Confiscation, much dreaded, was imposed on those condemned to perpetual imprisonment, on those who escaped sentence by flight and on those turned over to the secular arm. It could also be imposed on the heirs of those who died in heresy, as well as on those who had acquired the possessions of deceased heretics by purchase. Confiscation was not rare, and its proceeds served in part to defray the expenses of the Inquisition; local civil and ecclesiastical authorities also profited from it.

The public announcement of penalties was generally made at a solemn gathering, called *sermo generalis* ("general sermon") in medieval times but more commonly known in the history of the Inquisition by the Spanish equivalent, auto-da-fé (*q.v.*). As a rule this ceremony took place on a Sunday in a church or in the open. The inquisitor preached a short sermon, civil officials vowed obedience to the inquisitor, mitigations of earlier sentences were pronounced, and then recantations and sentences of condemned persons were announced and the condemned were turned over to the secular arm.

Geographical Limitation.—The medieval Inquisition did not function in Scandinavia, and in England it was used only in the case of the Templars (though under the statute *De haeretico comburendo* of 1401 the Lollards were persecuted; *see* LOLLARDS). In Germany, after the inauspicious start under Konrad von Marburg, it was used after 1450 against witches; in Bohemia it was employed against the Hussites, and in the 14th century it was used in the Netherlands against the Beghards. But it was in northern Italy, southern France and to a lesser degree Christian Spain that the Inquisition was most employed in medieval times. By the end of the 13th century it had overcome the Catharist threat to Christianity. In the later middle ages relatively little is heard of it except in connection with the trial of witches and the Spanish Inquisition.

Since most of the records of the medieval Inquisition have perished, it is impossible to give more than fragmentary statistics in regard to the numbers who suffered the death penalty, confiscation, etc. In the early days scores, occasionally hundreds of burnings at the stake are referred to. Later the extreme penalty was rarely applied; life imprisonment and confiscation of property were commoner. Among the victims of the medieval Inquisition were St. Joan of Arc, John Huss and Girolamo Savonarola.

Spanish Inquisition.—The medieval Inquisition had played a considerable role in Christian Spain during the 13th century, but the struggle against the Muslims kept the inhabitants of the Iberian peninsula busy and served to strengthen their faith. When toward the end of the 15th century the reconquest was all but complete, the desire for religious unity became more and more pronounced. It was at first the Jews who seemed to block the way to unity.

During the centuries the Jewish community in Spain had flourished and grown in numbers and influence, though anti-Semitism had from time to time made itself felt. Henry III of Castile and León (late 14th century) seems to have brought pressure to bear on the Jews to convert them. Then and later the threat of severe penalties hung over the Jewish community in Spain.

> The only alternative before the Jews was baptism or death. Thus the number of nominal converts to the Christian faith soon became very great. The secret Jews were incomparably more dangerous than those who openly professed their religion (L. Pastor, *The History of the Popes From the Close of the Middle Ages*, Eng. trans., vol. iii, p. 398 [1894]).

These nominal converts from Judaism were called marranos (*see* MARRANO). After Aragon and Castile were united by the marriage of Ferdinand and Isabella (1469) the marranos were denounced as a danger to the existence of Christian Spain, and a bull of Sixtus IV in 1478 authorized the Catholic kings to name inquisitors in whom they might repose confidence. This did not mean that the Spanish sovereigns were turning over to the church the struggle for unity; rather, they were seeking to use the Inquisition to support their absolute and centralizing regime, and most especially to increase the royal power in Aragon.

The first Spanish inquisitors, operating in Seville, proved so severe that Sixtus IV had to interfere. But the Spanish crown now had in its possession a weapon too precious to give up, and the efforts of the pope to limit the powers of the Inquisition were without avail. In 1483 he was induced to authorize the naming by the Spanish government of a grand inquisitor (inquisitor general) for Castile, and during the same year Aragon, Valencia and Catalonia were placed under the power of the Inquisition.

The president of the Inquisition in Spain was the grand inquisitor, designated by the government but receiving his ecclesiastical jurisdiction from Rome, which empowered him to name deputies and hear appeals. In deciding appeals the grand inquisitor was assisted by a council of five members and by consultors. All these offices were filled by agreement between the government and the grand inquisitor. The council, especially after its reorganization under Philip II, put the effective control of the institution more and more into the hands of the civil power. After Clement VII (1523–34), priests and bishops were at times judged by the Inquisition. In procedure the Spanish Inquisition was much like the medieval Inquisition. The first grand inquisitor in Spain was the Dominican Tomás de Torquemada (1420–98), who has become the symbol of the inquisitor who uses torture and confiscation to terrorize his victims; his methods were the methods of a time when judicial procedure was cruel and designed to inspire terror. The number of burnings at the stake during his tenure has been exaggerated, but it is generally put, by fair estimate, at about 2,000. (*See* also TORQUEMADA, TOMÁS DE.)

By edict of March 31, 1492, the Spanish Jews were given the choice of exile or baptism. When in 1502 Islam in its turn was proscribed, the Inquisition began to devote its attention to the moriscos (*q.v.*), the Spanish Muslims who had accepted baptism. When the Protestant Reformation began to penetrate into Spain the relatively few Spanish Protestants also were eliminated by the Inquisition. Nor did Catholics escape its rigours: Ignatius Loyola was twice arrested on suspicion of heresy, and the archbishop of Toledo, the Dominican Bartolomé de Carranza (*q.v.*), was imprisoned for almost 17 years.

Under the supreme council of the Spanish Inquisition were 14 local tribunals in Spain and several in the colonies, among which

those in Mexico and Peru have been particularly attacked. The Spanish Inquisition was introduced into Sicily in 1517, but efforts to set it up in Naples and Milan failed. The emperor Charles V in 1522 introduced it into the Netherlands, where its efforts to wipe out Protestantism were unsuccessful. John III of Portugal, with the permission of the pope, introduced a tribunal like the Spanish Inquisition against the Portuguese Jews in 1536. Though his methods led the pope to revoke the grant, the Inquisition was definitely established in Portugal in 1547, at which time its scope was also widened.

The Inquisition in Spain was suppressed by Joseph Bonaparte in 1808, restored by Ferdinand VII in 1814, suppressed again in 1820, restored again in 1823 and finally suppressed in 1834. The Portuguese Inquisition was suppressed in 1820.

Roman Inquisition.—The Roman Inquisition was established in 1542 by Pope Paul III to combat Protestantism; some have seen in its institution a desire to counterbalance the Spanish Inquisition at a time when a great part of Italy was under Spanish rule. It was governed by a commission of six cardinals, the Congregation of the Inquisition, whose powers in matters of faith extended according to their mandate to the whole Catholic world. The cardinal inquisitors were authorized to delegate their powers and to receive appeals from the sentences of their delegates. The Roman Inquisition was thoroughly independent and much freer from episcopal control than the medieval Inquisition had been. Under Paul III (1534–49) and Julius III (1550–55) its action was not rigorous, and Julius ruled that although the tribunal had general authority its action should be limited especially to Italy. The moderation of Paul III and Julius III was imitated by their successors with the exception of Paul IV (1555–59) and Pius V (1566–72). Under Paul IV the Inquisition functioned in such a way that it alienated nearly all parties.

> The hasty and credulous pope lent a willing ear to every denunciation, even the most absurd. Neither rank nor dignity nor merit weighed in the balance in the case of anyone suspected of heresy; he would be treated by the Inquisition as if he were the open and declared enemy of the church. The inquisitors, constantly urged on by the pope, scented heresy in numerous cases where a calm and circumspect observer would not have discovered a trace of it. . . An actual reign of terror began which filled all Rome with fear (L. Pastor, *The History of the Popes From the Close of the Middle Ages,* Eng. trans., vol. xiv, p. 287 [1924]).

While Pius V (a Dominican and himself formerly grand inquisitor) avoided the worst excesses of Paul IV, he nevertheless declared at the beginning of his reign that questions of faith took precedence over all other business and made it clear that his first care would be to see that heresy, false doctrine and error were suppressed. He was said, in fact, to have more zeal against heretics than against the Turks. He took part in many of the activities of the Inquisition, and it was thought that nothing pleased him more than to aid it. (*See* also PAUL; PIUS.)

The aims of Paul IV and Pius V, which were pursued with more moderation by the other pontiffs of the 16th and 17th centuries, were achieved. The religious unity of Italy was maintained without resorting to the Spanish Inquisition. The best-known victims of the Roman Inquisition are Pietro Carnesecchi, Aonio Paleario and Giordano Bruno.

After Protestantism had been eliminated as a serious danger to Italian religious unity, the Roman Inquisition became more and more an ordinary organ of papal government concerned with maintaining good order and good customs as well as purity of faith among Catholics. The best-known case in the 17th century is undoubtedly the condemnation of the Copernican system and of Galileo (1616, 1632). In his reorganization of the Roman curia in 1908, St. Pius X dropped the word "Inquisition," and the congregation charged with maintaining purity of faith is now known officially as the Holy Office (*Congregatio sancti officii*).

Conclusion.—Not only non-Catholics but many Catholics have judged the Inquisition severely. These condemnations have at times been motivated by an exaggerated idea of its rigours. More frequently they may be said to be due in part to the fact that the Inquisition has been considered apart from the judicial context of the times. The principles and practices of the Inquisition were no crueler than those of the contemporary civil courts; if it is condemned on such grounds, the middle ages and the Renaissance must also be condemned. Not only Catholics but the early Protestants and many other religious groups used force to impose religious unity.

On purely religious grounds the problem is sharper. Has a church the right and duty to use more than moral suasion against erring brethren? Have the orthodox the right to inflict temporal punishment on heretics? Does charity demand discipline rather than tolerance? In the case of purely religious conflict all these questions might readily be answered in the negative, but religious conflict almost always has social and political overtones. Religious rebels often threaten the existing order, and the issue is almost never clear-cut. Theologians of the middle ages, even apart from these considerations, were in favour of eliminating pertinacious heretics, arguing that to corrupt the faith is a much more serious crime than to counterfeit money or commit many other offenses that were then punishable by death. They insisted, however, that efforts should be made to bring the heretics to recant and that the death sentence should be carried out by the civil authorities. During the Renaissance period Catholic theologians argued that death is the only efficacious deterrent in the case of heresy—excommunication, fines and exile had been tried and found useless. Catholic theologians of the present day do not subscribe to either the medieval or the Renaissance arguments.

INSANITY. Although formerly a part of scientific nomenclature, the word "insanity" is today employed principally as a term of legal significance. So used, it denotes those conditions of mental disorder or defect which modify certain of the legal relations, rights and obligations of afflicted persons. For discussions of mental disorder in its medical and psychological aspects, *see* MENTAL DEFICIENCY; PSYCHIATRY; PSYCHOANALYSIS; PSYCHOLOGY; PSYCHOLOGY, ABNORMAL; PSYCHOSES.

In general, the legal rules which define the rights, privileges and obligations of persons assume the existence of a degree of mental capacity sufficient to enable the person to manage his conduct and affairs in the ordinary contingencies of life. When, by reason of mental disease or defect, such capacity is lacking, however, the law applies special regulations which deny to the insane person some of the rights and privileges enjoyed by other members of the community, and, at the same time, relieve him of certain obligations and responsibilities. These various rules are encountered both in the criminal and civil law. The degree of mental incapacity required to be found and the modes of proof vary from situation to situation. There is, thus, no single legal test of insanity. Reference must always be made to the particular purpose for which the inquiry is made. Even with respect to the same rule, legal authority is sometimes sharply divided.

INSANITY IN THE CRIMINAL LAW

The most dramatic application of the insanity concept, though not necessarily of the greatest practical importance, is that which relieves the afflicted person of criminal responsibility for his conduct. It is important to understand that the legal tests of responsibility are not, and are not intended to be, scientific definitions of mental disorder. Rather, the legal tests are expected to identify those persons whose incapacities, produced by mental disease or defect, are of such character and extent that criminal responsibility should be denied on grounds of social expediency and justice. The inutility and moral incongruity of holding seriously disordered persons to the criminal consequences of their acts have been recognized in the development of the Anglo-American law for at least seven centuries. Responsibility assumes capacity to make elementary moral discriminations and power to adjust behaviour to the commands of the law. One lacking such capacities

is conceived as ineligible for the moral condemnation inherent in a criminal conviction. Such persons, also, are not likely to be deterred from the commission of criminal offenses by the threat of penal sanctions.

Early History.—Beginning with the writings of Henry de Bracton in the 13th century, discussion of the legal consequences of mental disorder appear in the work of several early commentators. The 17th-century treatise of Lord Hale, however, contains perhaps the first systematic effort to state a legal test of criminal responsibility in the English law. Hale wrote: ". . . such a person as labouring under melancholy distempers hath yet ordinarily as great understanding, as ordinarily a child of fourteen years hath, is such a person as may be guilty of treason or felony." This observation was made the basis of the so-called child of 14 years test in later cases.

In *Arnold's Case* (16 How. St. Tr. 695), decided in 1724, Justice Tracy, relying on a suggestion of Bracton, announced a formulation sometimes referred to as the "wild beast test." Not every kind of "frantic humour," said Justice Tracy, exempts a man from punishment; "it must be a man that is totally deprived of his understanding and memory, and doth not know what he is doing, no more than an infant, than a brute, or a wild beast . . . ." In *Hadfield's Case* (27 How. St. Tr. 1282), tried in 1800, Thomas Erskine, the brilliant criminal advocate, induced the court to accept the proposition that "delusion . . . , where there is no frenzy or raving madness, is the true character of insanity."

McNaghten Rules.—But it is the rules announced in the famous case of *McNaghten* (10 Cl. and Fin. 200) which constitute unquestionably the most important pronouncement on the subject of criminal responsibility in the Anglo-American law. Though formulated in 1843, the McNaghten rules still provide the basis for the modern law in most English-speaking jurisdictions. Daniel McNaghten, acting under a delusion that he was being persecuted by Sir Robert Peel, shot and killed Peel's secretary, Edward Drummond, believing him to be Sir Robert. McNaghten was brought to trial on a charge of murder, but was acquitted by a verdict of not guilty on the ground of insanity. The public interest and outcry were of such proportions that the house of lords was induced to employ the unusual procedure of addressing a series of questions to the judges of England on the subject on insanity. The answers to these questions, announced by the chief justice, Sir Nicholas Tindal, constitute the McNaghten rules. It has been suggested that the judges' answers, since submitted in response to hypothetical questions and not in the course of adjudicating an actual case, have no binding legal effect. As a practical matter, however, the rules have been accepted as authoritative in most Anglo-American jurisdictions. A portion of the judges' answer to the second and third questions is most important for the purposes of modern law: ". . . to establish a defence of insanity, it must be clearly proved that, at the time of the committing of the act, the party accused was labouring under such a defect of reason, from disease of mind, as not to know the nature and quality of the act he was doing; or if he did know it, that he did not know he was doing what was wrong." It will be observed that it is the mental condition of the accused at the time of commission of the act which is crucial and that the incapacity must be the result of mental "disease." There have been many widely diverging interpretations of the other important terms of the formulation. Thus, in the United States, "wrong" is frequently understood in the sense of moral wrong, while in Britain mid-20th century cases have held that the accused is not entitled to exculpation if he knew his act was contrary to law.

The McNaghten rules have been the source of sharp and sometimes intemperate controversy for over a century. The range of criticism has been wide and the points made have possessed varying degrees of cogency and relevance. It is said, for example, that the McNaghten rules, by their exclusive reliance on the criterion of knowledge, emphasize unjustifiably the cognitive or intellectual elements of human personality, at the expense of the will and emotions, and, consequently, incorporate an obsolete conception of the nature of mental disorder. Since the rules are founded on conceptions foreign to modern medical science, the psychiatric witness finds it difficult or impossible to translate his learning into the terms of the legal formula, thereby depriving the court and the jury of the full benefit of his expert insight. Also, it is said that the rules require a total incapacity to distinguish wrong from right, although even grossly disordered persons may possess at least rudimentary powers of moral discrimination.

Changes From the McNaghten Rules.—Although the attack on the McNaghten rules has received much less than unanimous support, an important segment of opinion has held for many years that drastic changes in the legal tests of criminal responsibility are required. In the United States the adoption of the irresistible impulse test by the federal courts and those of about one-quarter of the states is one important consequence of this dissatisfaction. The irresistible impulse test is accepted in no jurisdiction as a total substitute for the McNaghten rules. Rather, it is intended to supplement the right and wrong test by relieving from criminal responsibility those who may have power to discriminate intellectually between right and wrong but who, because of mental disorder, are unable to act on that knowledge and to control their behaviour. As expressed by a Utah court: "Volitional ability to choose right and avoid wrong is as fundamental in the required guilty intent . . . as is the intellectual power to discern right from wrong and understand the nature and quality of his acts" (78 Utah 580, 6 P. 2d 177).

The irresistible impulse test has also received its share of criticism, and the critics have included both supporters and opponents of the McNaghten rules. Some have urged the difficulties of distinguishing between the irresistible impulse and the impulse which is merely unresisted. More fundamentally, others have complained of the emphasis on "impulse" as erroneously suggesting that volitional disorders are manifested only in sudden or momentary inclinations to commit unlawful acts. Still others have urged that a proper interpretation of the McNaghten rules renders the irresistible impulse test unnecessary, since serious volitional disorders are always accompanied by impairment in the cognitive capacities of the afflicted person.

In recent years the movement to reform the legal tests of criminal responsibility has received increased impetus in the countries of the Anglo-American legal system. In the United States one important judicial development was the 1954 decision in *Durham* v. *U.S.* (214 F. 2d 862) by the U.S. circuit court for the District of Columbia. That decision, applicable only to the District of Columbia and not to the federal courts generally, rejected the McNaghten rules as supplemented by the irresistible impulse tests, which had formerly been applied in the jurisdiction, and adopted a new formulation derived from opinions of the New Hampshire court, the only U.S. jurisdiction that had theretofore rejected the McNaghten rules. The Durham test, as it has come to be known, is "simply that an accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect."

The decision was hailed by many in the medical profession and by some lawyers as an event of profound importance. It was pointed out that the formulation, by avoiding reference to any particular symptom of mental disorder, eliminates the danger of incorporating into the legal test conceptions of mental disease which are or which may shortly become obsolete. It was also urged that the test provides the psychiatric expert with greater freedom in conveying his scientific evaluation of the accused's condition to judge and jury. Despite its claimed advantages, no other U.S. court had adopted the Durham formulation by the beginning of the 1960s. Some commentators have pointed to difficulties in the notion of causation inhering in the phrase "the product of." Because the formulation states no requirements with reference to the degree of incapacity produced by the mental disorder, questions have been raised as to the breadth of the exculpation it may theoretically authorize.

Trial Practice.—The mode of trying the insanity issue in criminal trials has provoked very nearly as much criticism as the tests of responsibility. The use of the lay jury to decide the issue of responsibility, the adversary nature of the judicial proceedings, the use of partisan expert witnesses, the elaborate "hypothetical questions" which may be put to the psychiatric witness and other

procedural matters have been attacked frequently and with considerable asperity.

While some of the criticism reveals misunderstanding of the purposes and function of legal proceedings in these cases, it cannot be denied that many of the complaints point to weaknesses which can and should be remedied. In the United States, provisions of state constitutions, such as those relating to the right of jury trial, place certain limitations on innovation. Thus, statutes of Washington and Mississippi, which entirely eliminated the defense of insanity from the trial of criminal cases, were held unconstitutional. A California statute has been sustained, however, which requires the insanity issue to be tried in a separate proceeding, after it has been determined in the original trial that the accused committed the criminal acts charged.

Partial Insanity.—Mental disorder may affect criminal liability even though the incapacity of the accused is not of such degree as to relieve him entirely of criminal responsibility. The definitions of certain offenses require proof of particular mental states on the part of the accused. In some jurisdictions, the doctrine of "partial" insanity entitles the defendant to a jury instruction on the issue whether his mental disorder rendered him incapable of entertaining the particular mental state included in the definition of the crime. Thus, in a prosecution for murder in the first degree, the issue would be whether the accused was, by reason of mental disorder or deficiency, rendered incapable of premeditating or deliberating the killing, which is an essential element of the crime. If the jury determines that the accused was incapable of premeditation, it may return a verdict holding him guilty of second-degree murder or some lesser degree of criminal homicide. The U.S. supreme court has refused to reverse a criminal conviction for first-degree murder where the trial judge refused such an instruction (*Fisher* v. *U.S.*, 328 U.S. 463). But the trend of judicial authority in the United States appears to be toward the contrary result. In England, the Homicide act, 1957, introduced the doctrine of "diminished responsibility" into the law of England and Wales. It had long been part of the law of Scotland. Section 2 of this act provides in essence that an accused shall not be convicted of murder if he suffered from such abnormality of mind as substantially impaired his mental responsibility for his acts in doing or being a party to the killing. If the accused succeeds in establishing this condition he shall be found guilty of manslaughter. In *R.* v. *Byrne* (2 Q.B. 396 [1960]) the phrase "abnormality of mind" was broadly read to encompass cases in which the abnormality creates substantial difficulties for the accused in controlling his physical acts.

Continental European Tests.—Tests of responsibility are included in the criminal legislation of countries whose legal systems are not derived from the English common law. These tests typically give consideration to both cognitive and volitional incapacities. Thus, article 85 of the Italian penal code relieves a person of responsibility when he "is deprived of the capacity of understanding or volition." The factors which most significantly distinguish the continental law of insanity from that of the English-speaking jurisdictions are procedural, not the least important of which derive from the fact that in continental Europe no provision is ordinarily made for the use of lay juries to resolve the issue of criminal responsibility. In some but not all the continental codes, mental disorder, which is insufficient in degree to relieve the accused of responsibility, may be taken into account by the sentencing authority to mitigate punishment.

"Present Insanity."—The significance of mental incapacity in the criminal law is not restricted to the question of the mental condition of the accused when the criminal act was committed. At the common law a person afflicted with what is sometimes called "present insanity" cannot be required to plead to an indictment or stand trial on a criminal charge.

The legal test of "present insanity" is wholly distinct from the tests of criminal responsibility. While the test of "present insanity" has been expressed with some variations in language, "present insanity" consists in essence of that degree of mental disorder which denies the accused understanding of the nature of the proceedings against him or renders him incapable of making or assisting in his own defense. The principle which protects such persons from standing trial has been widely adopted in modern legislation. Indeed, under U.S. constitutional provisions, the principle has been recognized as part of the concept of fair trial and due process of law. The question of "present insanity" may be raised by the defense, the prosecution or the trial judge. It has been held that the judge has not only a privilege to raise the issue, but, when he reasonably suspects the mental capacity of the accused, he is under duty to do so. At common law the issue of "present insanity" was tried before the trial judge, with or without a jury at the judge's discretion. Some of the statutes in the United States preserve the common-law powers of the judge in this matter, others require the summoning of a jury and still others require the trial judge to obtain the assistance of psychiatric specialists in determining the issue. It is important to understand that a finding of "present insanity" only postpones the criminal proceedings until such time as the accused has sufficiently recovered from his incapacities.

One of the important problems in the administration of criminal justice is the detection of mentally disordered persons among those apprehended and brought to trial on criminal charges. Although the right to raise the issue of "present insanity" is clearly established, there is reason to believe that substantial numbers of persons are tried who should not be subjected to criminal proceedings. Even larger numbers of seriously disordered persons are arrested and released from custody who, in their own interests and those of the community, should be confined in mental institutions. In response to these needs, court clinics and other facilities have been established in many localities for the purpose of providing pretrial psychiatric examinations, either on a routine basis or when requested in special circumstances. Most observers agree that such facilities have made a substantial contribution to the effective administration of the criminal law. Perhaps the most interesting statute on this subject is the famous Briggs law of Massachusetts. The law, enacted in 1921, requires the routine examination of all persons charged with certain specified criminal offenses. The examinations are conducted by specialists employed in the state department of mental health. A report of the examination is forwarded to the court and may be introduced in evidence if the accused is brought to trial. The procedure not only assists in the detection of those who are presently insane, but, it is claimed, the tendency of juries to regard the reports as impartial and to give them great weight has done much to eliminate the "battle of the experts" when the issue of criminal responsibility is raised at the trial.

Insanity After Sentence.—There are other situations in which mental disorder has important consequences in the administration of criminal justice. One of these is presented by cases in which a prisoner under sentence of death is found to be incapable, by reason of mental disorder, of understanding the nature and purposes of the punishment about to be inflicted upon him. At common law, the death penalty may not be inflicted in such situations, so long as the mental disorder persists. The reason for the rule, suggested by Lord Coke, is that the execution of a disordered person "cannot be an example to others." Another reason, sometimes advanced, is that the disordered prisoner is incapable of communicating facts to his counsel which might be useful in securing executive clemency. There is a wide variety of statutes in the United States regulating the mode of determining insanity in these cases. Many require a jury trial of the issue. Others authorize the issue to be determined in the courts, with or without juries in the judges' discretion. Still others have eliminated judicial trial of the issue and place its determination, after some species of administrative hearing, in the governor or other executive personnel. Such a state statute has been upheld by the U.S. supreme court (*Solesbee* v. *Balkcom*, 339 U.S. 9). Questions may arise, also, as to whether the prisoner has sufficiently recovered his faculties to permit the execution to proceed. Although there is no definitive constitutional ruling on the point, this determination probably must be preceded by a hearing, though not necessarily by a judicial hearing.

Insanity and Acquittal.—A procedural problem of some importance relates to the disposition of defendants who are acquitted on the criminal charge by reason of insanity. If the defendant is

still suffering from mental disorder, his interests and those of the community may require that he be confined in a mental institution until his recovery. In the United States this problem has been the subject of a wide range of statutory provisions. The prevailing legislative pattern confers discretion on the trial judge to order the civil commitment of the defendant in such cases, though in many statutes the order of committal can be entered only after the judge has conducted an investigation into the defendant's present mental condition. Some of the states require the jury at the criminal trial to consider the defendant's present mental condition. If the jury finds that the accused at the time of acquittal is still afflicted with mental disorder, the trial judge must order the defendant committed to a mental institution. A few states have so-called "automatic commitment" statutes, which require the immediate confinement of defendants acquitted on grounds of insanity without any further hearing or investigation. These laws, in effect, create a presumption of continuing mental disorder, and have been upheld as constitutional in the state courts. A person who has, in fact, recovered from the mental illness may be released by the hospital authorities, or may challenge the legality of his confinement in the courts, ordinarily in a habeas corpus proceeding in which recovery from the mental disease is alleged. In England, no provision was made for civil commitment of such persons before 1800, and a defendant acquitted on grounds of insanity was permitted to go at large. After that date the trial judge had power to detain the defendant "during His [or Her] Majesty's pleasure." The Trial of Lunatics act, 1883, authorized a new form of verdict—"guilty, but insane"—in cases in which the defendant successfully maintains an insanity defense, and, in effect, directed the automatic commitment of such defendant to the custody of the home secretary. The form of verdict authorized by the 1883 act is inaccurate and illogical; it is, in fact, a verdict of acquittal on the criminal charge, from which an appeal by the prosecution may not be taken. The Royal Commission on Capital Punishment (1949–53), following the recommendations of the earlier Atkin committee, urged an amendment to the law "so that the verdict may again be one of acquittal in language as well as in substance." (F. A. A.)

INSANITY IN THE CIVIL LAW

Questions relating to the legal consequences of mental disorder are encountered throughout the civil law. These problems may be roughly classified into two broad categories: those relating to the protection and care of the disordered person in the interests of his well-being and the safety of the community, and those relating to the capacity of the insane person to perform certain legal acts and to enter and avoid certain legal relations. As in the criminal law, there is no single legal test of insanity applicable to all situations in which the mental capacity of a person may be in issue.

Protection of the Well-being of the Insane and of the Community.—The obligation to afford care and protection for seriously disordered persons has long been recognized. But involuntary commitment to a mental institution subjects the person to loss of liberty. Many of the problems relating to commitment procedures stem from the necessity of reconciling the need for protective measures and for reasonably adequate procedural safeguards.

At mid-20th century, statutes in Anglo-American jurisdictions provided a variety of procedures for the commitment of the mentally ill. These statutes had replaced common-law rules which provided for petition to the chancery court, issuance of a writ *de lunatico inquirendo* and trial of the fact of insanity by a jury. A procedure for indeterminate commitment authorized by almost all of the U.S. statutes involved a hearing before a judge or a quasi-judicial agency following petition by an interested party, notice to the allegedly insane person and examination of the person by two physicians (not necessarily psychiatrists). In appropriate cases, the court or commission issued an order of commitment. The mandatory requirement of a jury trial, which had been incorporated in the statutes of many states in the 19th century as a result of well-publicized charges of allegedly improper commitments, had been eliminated in all but two states. In several others, a jury might be demanded by the person proceeded against. Some jurisdictions furnished counsel to those requesting representation.

Indeterminate commitment without a hearing was permitted in about 15 states. In those cases the order of commitment was made by physicians or health officers, and a judicial hearing was held only if the patient appealed from the order. This simplified procedure, commonly used in continental European countries, was authorized in England by the Mental Health act of 1959.

The circumstances justifying indeterminate commitment were variously defined. The Draft Act Governing Hospitalization of the Mentally Ill, which had been adopted in whole or in part by one-fourth of the states in the U.S. since its proposal in 1950, provided that commitment could be ordered if the mentally ill person was likely to injure himself or others, or if he was in need of hospital care but had lost the power to make an intelligent decision concerning it. Many other U.S. jurisdictions used similar criteria.

Short-term commitment without a hearing was authorized by almost all of the states, where immediate hospitalization was deemed necessary, usually on the certificate of a single physician. The procedure permitted detention for only a short period, usually five days, unless a formal commitment order had been obtained in the meantime. A few states provided for "non-protested" commitment, whereby a relative or friend might commit a person summarily if he did not protest. A number of others permitted commitment without a hearing for a longer period of time for diagnostic purposes, but the requirements were more stringent. Voluntary commitment, requested by the person himself, was provided for in a number of states. Under this procedure, a person might be detained for a fixed period, typically 60 days, or for a brief period after he requested release.

Reimbursement by the patient or his close relatives of the state's expense in hospitalizing the patient was required almost universally. Sterilization of certain insane and mentally deficient persons was permitted in about half the states by laws enacted during the first half of the 20th century. The Virginia sterilization law was held not to offend the U.S. constitution in *Buck* v. *Bell* (274 U.S. 200), decided by the U.S. supreme court in 1927.

Release after indeterminate commitment ordinarily followed an administrative finding by hospital authorities that the patient had regained his sanity. A patient denied release though he had recovered from his disorder could resort to the courts, generally through habeas corpus proceedings.

Commitment to a mental hospital did not, in most instances, result in an adjudication of incompetency. The latter was more frequently decided in a separate judicial procedure for the appointment of a guardian. The guardianship might relate either to the person or to the property of the insane individual, or both. The test of mental capacity authorizing the appointment of a guardian was ordinarily said to be whether the person, by reason of mental disorder, was unable to manage his own affairs or to care for his estate. Guardianship procedures were governed by statute in all states, and the procedures resembled those for indeterminate commitment by court order.

Legal Capacity of Insane Persons.—Capacity to enter contracts or to convey property may exist though a person is mentally defective or disordered, or even, in some U.S. states, though he has been committed to an institution or judged incompetent. The laws of the Anglo-American jurisdictions on this subject represent attempts to reconcile policies favouring security of business transactions and protection of the mentally ill. It is not surprising that there are disagreements on the weight to be assigned to each. Thus it appears to be the current English view that an agreement cannot be avoided by the insane party if it was fair to him and his disorder was unknown to the sane party, whereas most U.S. jurisdictions permit avoidance by one whose mental incapacity prevented him from understanding its nature and effect, usually conditioned upon his return of any benefits received. Normally the insane person may hold the other party to the bargain.

Most jurisdictions provide by legislation that persons of unsound mind lack capacity to dispose of property by will. The relevant test is whether the testator is of sufficiently sound mind

and memory to understand the nature of his act, to comprehend the character and extent of his estate and to recollect the natural objects of his bounty.

In all U.S. jurisdictions, a marriage can be annulled at the instance of a party who was at the time of the ceremony unable to understand its nature and resulting rights and obligations, and who has not ratified the marriage after regaining sanity. In about half of the states the sane spouse also can, in these circumstances, probably obtain an annulment; sometimes the statutes require him to have been ignorant of the other's disorder at the time of the marriage. Prolonged and incurable insanity, occurring after marriage, is recognized in a majority of states as a ground for divorce. In England, the law has long permitted annulment at the instance of either spouse if one was unable to understand the ceremony and the ordinary incidents of marriage, and there had been no ratification. The Matrimonial Causes act of 1937 greatly enlarged the rights of the sane spouse by allowing, if certain requirements are met, annulment where the other was of unsound mind or a mental defective or subject to recurrent fits of insanity or epilepsy, even though he had understood the ceremony and its consequences. In addition, the act permitted for the first time in England divorce for incurable insanity occurring after marriage, if the respondent was continuously under care and treatment for at least five years immediately preceding the action.

Insane persons are generally held liable for their torts; *i.e.*, harm they inflict on others. It is apparent that the proposition results in the imposition of civil liability on those who, by reason of mental disorder, may be incapable of avoiding the torts. This rule may be explained, in part, as a historical survival from a period in which tort liability was generally imposed without regard to the fault of the actor. A number of additional reasons have been advanced, none of which appear wholly satisfactory. It is said that since insanity may be feigned, a contrary rule of law might be used improperly by a sane person to escape liability. Also, placing responsibility on the insane person may induce the guardian, or others interested in the person's welfare, to exercise closer supervision of his activities. Finally, public policy requires that, as between two innocent persons, loss should be borne by the one who occasioned it. In the adjudicated cases, insane persons have been held liable for a wide variety of torts including assault and battery, trespass on land and even alienation of affections. An insane person is liable for negligent harms, and the standard of care is apparently that which is required of a sane person. One exception to the rule of liability relates to certain wrongs requiring proof of a "specific" intent, which a disordered person may be incapable of forming. These include such torts as malicious prosecution and defamation.

Finally, mental disorder may have important consequences as it relates to the capacity of insane persons to give testimony in judicial proceedings. The early common-law rule rendered any person of unsound mind totally incompetent as a witness. Although a literal reading of some modern statutes would require the same result, it appears that nowhere is the rule applied in its original rigour. The broad principle generally applied today would exclude a witness only where the disorder substantially impairs the trustworthiness of the particular testimony. Some of the cases suggest that a person of unsound mind is competent to testify if it is found that he understands the nature and significance of his oath and has sufficient possession of mind and memory to recollect and relate what he saw and heard.

(C. L. KE.)

INSCRIPTIONS are documents incised on some hard or permanent material in the form of letters or other conventional signs, for the purpose of conveying some information or preserving a record. (Although inscriptions come from many parts of the world, *e.g.*, India, Mexico, Turkey, China, this article deals only with those from the ancient near east, Greece and Rome, since these have been by far the most thoroughly studied.) Inscriptions are to be distinguished on the one hand from manuscripts, or documents written on papyrus, parchment, paper or other more or less smooth surfaces by means of a brush, reed or pen and some coloured fluid (*see* PALEOGRAPHY; PAPYROLOGY), and on the other hand from pictures or reliefs intended to convey information or to record events (*see* PICTOGRAPHY), though inscriptions were often combined with such pictures or reliefs, especially in primitive times. There are also some classes of documents which are intermediate between inscriptions and manuscripts, such as writing incised with a stylus or sharp-pointed instrument upon tablets covered with a thin coating of wax or scratched upon pottery or other hard materials (*ostraka*). But as the forms of the letters and the character of the writing in both these cases approximate to what is found in manuscripts, they are usually considered to belong to that class of document; but graffiti, or casual scratching on walls, rocks or fragments of pottery, are sometimes included in the study of inscriptions because they often fill gaps and, in early times at least, did not differ in form or character from ordinary inscriptions. A good example is offered by the names and other records scratched by Greek mercenaries at the time of Psammetichus II (6th century B.C.) on the legs of the colossal statues at Abu Simbel in Egypt. As one of the earliest examples of the use of the Greek alphabet, these find their place in the history of inscriptions. On the other hand, casual notes as well as receipts, accounts, etc., are found scratched upon potsherds or *ostraka*, which were merely a cheap substitute for more expensive material such as papyrus; the study of such *ostraka* cannot be separated from that of manuscripts on papyrus, and really forms a branch of paleography rather than of epigraphy.

Inscriptions were studied and quoted by authors in ancient times, by orators and by historians—notably Thucydides and Polybius—as records of political, economic and social interest; they also contributed to the history of art, and Polemon of Ilium had the nickname of *stelokopas* ("tablet-picker") given him for his studies of such documents. His work is now lost. Some of the great scholars of the Renaissance were interested both in Greek and Roman inscriptions. But the gigantic task of collecting and editing all known ancient inscriptions has been undertaken only since the 19th century.

FORM

Materials and Technique.—Inscriptions were commonly incised on stone or marble, on metal or on wood (though this last material has hardly ever survived except in Egypt) or on terra cotta. In Egypt and Mesopotamia hard stones were frequently used for the purpose, and the inscriptions are therefore well preserved and easy to read. In Greece the favourite material, especially in Athens, was white marble, which takes an admirably clear lettering but is liable to weathering of the surface, if exposed, and to wear, if rebuilt into pavements or similar structures. Many other kinds of stone, both hard and soft, were often used, especially crystalline limestones, which do not easily take a smooth surface and which, therefore, are often difficult to decipher, because of accidental marks or roughness of the material.

The metal most commonly used for inscriptions was bronze; flat tablets of this metal were often made for affixing to the walls of temples and other buildings. Occasionally such tablets were made of silver or gold, and inscriptions were often incised on vessels made of any of these metals. Inscriptions on metal were nearly always incised, not cast. An important class of inscriptions are the legends on coins; these were struck from the die. (*See* NUMISMATICS.) Clay was very extensively used for inscriptions in the near east and in Crete. In this case the symbols were incised or impressed on specially prepared tablets when the clay was soft, and it was subsequently hardened by fire. In Greece many inscriptions on vases were painted before firing (especially when they had reference to the scenes represented), or incised after firing; potsherds were often used as a cheap writing ma-

terial. Inscriptions were also impressed from a mold upon wet clay before firing; this frequently was the case with tiles, amphora handles, etc., objects which often supply valuable information as to the buildings to which they belong or the place from which they took their origin.

The tools used for making inscriptions varied with the material; most of them were chisels of some sort, usually with a square blade; early inscriptions were sometimes made on hard rock by successive blows with a punch or pointed hammer. Sometimes a circular punch was used for *O* or a letter of which *O* formed a part.

Early inscriptions, which were often amateur work, are frequently very irregularly cut. But in almost all examples of later work the inscriptions were evidently cut by professionals and there are definite styles and methods belonging to various places and periods. In Egypt, for instance, the hieroglyphs (*q.v.*) were carefully and delicately cut in early times, but became more careless and conventional in later periods. In Greece the best work was done in the 5th and 4th centuries B.C. in Athens. The letters were all exact and regular in shape, with no adventitious ornaments, and, especially in the 5th century, were usually aligned exactly with the letters above and below as well as with those on each side. The result is a beauty and simplicity of effect that has never been surpassed. At that time all the strokes were made of equal thickness, but in the 4th century B.C. and later there arose the custom of holding the chisel obliquely to the surface, thus producing a wedge-shaped stroke. A similar custom in Mesopotamia gave rise to the cuneiform (*q.v.*) system. In Greece this effect appears earlier on metal inscriptions than on stone or marble. In the 3rd century and later it became common to introduce apices, or ornamental ends, to the strokes, a custom which prevails to the present day in ordinary capital letters. The custom of making different strokes and different parts of curves of varying thickness became common in Roman inscriptions, which developed a monumental style of their own, varying from period to period. Inscriptions can often be dated approximately by the style of the cutting as well as by the shapes of the letters; skill in doing this can only be acquired by a careful and minute study of originals and facsimiles.

Inscriptions vary greatly in size according to their intended position, their purpose and the skill of the cutter. Some inscriptions are of great length, the longest—a statement of accounts of the temple at Delos under Athenian administration—being nearly half as long as a book of Thucydides; and many other inscriptions approach this in length.

Symbols and Forms of Writing.—The origin of writing (*q.v.*) and the evolution of the alphabet (*q.v.*) need not be discussed here. For the present purpose it is sufficient to note that most of the known forms of writing originated in some system of picture writing. Such systems appear independently in different parts of the world—in Egypt, Mesopotamia, Crete, among the Hittites and in China and America. The evidence for all of these is to be found mainly in inscriptions. The development from ideograms (or direct representation of an object or idea) to symbols of phonetic value, and so to syllabaries or alphabets, took place in many different systems to various degrees. The Greeks borrowed the Phoenician system of writing, with certain modifications and improvements. From the Greek was derived the Latin; and from the two, all the later alphabets of European peoples. It is still a matter of dispute whether the Phoenician was derived from the Egyptian.

The pictographic shapes naturally tended to be conventionalized and simplified for convenience of cutting, in accordance with the materials and tools employed. In many cases they developed from a pictorial to a linear form. It is possible that some of these linear forms may not be derived from pictograms at all, but from purely conventional geometrical forms, such as were widely used at all periods and places as owners' or masons' marks. The tendency of linear forms to become wedge-shaped is most conspicuous in cuneiform, but the same tendency occurred in Greek inscriptions of the 3rd and 2nd centuries B.C., and earlier in inscriptions incised on bronze.

In the north of Europe the Ogham inscriptions are alphabetic, and are apparently an independent invention on arbitrary lines, like the Morse code; but Runes, which were extensively used in the same region, are derived from the Greek or the Latin alphabets. (*See* OGHAM WRITING; RUNE.)

Certain symbols which are not strictly alphabetic or phonetic in character are also found in inscriptions of most alphabetic systems. The commonest of these are the various systems of numerals that were used in different times and places. It is impossible to give any full description here of these different systems, but a brief account may be given of the principles underlying them. Most of them are based upon a decimal system, doubtless owing to the habit of counting on the fingers. In some cases the symbols are simple and obvious, as in the Cretan script where circles and short horizontal and vertical strokes are used for hundreds, tens and units, each being repeated as often as necessary; and a similar system for the lower denominations was used at Epidaurus in the 4th century B.C. In Athens the usual system was to indicate each denomination by its initial, M for *myrioi* (10,000), X for *chilioi* (1,000), H for *hecaton* (100), Δ for *deca* (10), Π for *pente* (5) and I for units. The other Greek system followed that derived from the Phoenicians, using the letters of the alphabet in their conventional order from 1 to 9, 10 to 90 and 100 to 900; in this arrangement obsolete letters were retained in their original places so as to give the requisite number of 27 symbols. The Roman system of numerals—M, D, C, L, X, V, I (for 1,000, 500, 100, 50, 10, 5 and 1)—is generally supposed to have arisen from the adaptation of certain symbols in the Greek alphabet.

Apart from numerals, the use of initials in the place of complete words was not common in early times. However, it became very frequent in Roman inscriptions, which sometimes are made up almost entirely of such abbreviations and can only be understood by those familiar with the formulae. Compendia or monograms also occurred in later Greek and Roman times, and became very common and difficult to interpret in early Christian and Byzantine inscriptions.

Some kind of punctuation is often found in inscriptions of all kinds. In Greek inscriptions a vertical line or a dot (or group of dots) sometimes indicates the separation between sentences or words; but words are seldom separated by spaces as in modern printing, so that the text is continuous and no division of words exists. This is particularly the case with Greek inscriptions of the best period. In Roman inscriptions it was usual to separate the words by dots. In certain inscriptions a cross (+) was used to indicate the beginning of an inscription, especially when its direction was erratic. Christian inscriptions sometimes began with a cross, which doubtless had a symbolic meaning, and a leaf or other device was often placed at the end.

The direction of the writing varies greatly in different places and times. The letters or symbols may be arranged vertically below one another, reading from top to bottom, or horizontally, reading either from right to left or left to right; they may also be arranged in a kind of pattern—in which case their order may be indeterminate, or follow a wandering or curved line, or read left to right and right to left alternately (*boustrophedon*, or as an ox in plowing). Most Semitic alphabets, including Phoenician, read from right to left; and the earliest Greek inscriptions follow the same direction. But the direction from left to right became regular in Greece after the 6th century B.C., and consequently was adopted by the Romans and in all European systems. The individual letters or symbols usually face in the same direction as the writing as a whole.

Position or Place.—When they have a direct relation to the sculptures, reliefs or paintings with which they are associated, inscriptions often form a kind of pattern to fill the background or vacant spaces between the figures. Sometimes, however, and especially in Mesopotamian statues or reliefs, they are cut right across the figures without any regard to the artistic effect. In late Greek or Roman work it was usual to cut any inscription relative to a statue or relief upon the base on which it was mounted, but short inscriptions such as dedications or artists' signatures were often placed in some inconspicuous position upon the work itself. In

the case of painted vases the inscriptions relative to the subject represented were usually painted; but dedications and other inscriptions were often incised after the vase had been fired.

In Egypt, inscriptions were often inscribed or painted upon the inner walls of tombs, whether they referred to religious belief or ritual or to the honours and possessions of the deceased. They were intended for his benefit and convenience rather than for the information of others—to perpetuate his familiar surroundings, not to make him live in the memory of his successors. The information which is derived from such inscriptions is invaluable, but such was not the intention with which they were made. On the other hand, inscriptions which were intended to be seen by the public and to perpetuate a record of events or to supply useful information usually occurred in places of common resort, above all in temples and sacred precincts. Sometimes they were cut on convenient rock faces, sometimes upon the walls of temples or other buildings. Most frequently the slabs of marble (*stelae*), stone, metal or other material upon which the inscriptions were incised were set up in convenient positions to be read in places of public resort. This was the method of publication of all laws, decrees and official notices, of treaties and contracts, of honours to officials or private citizens, of religious dedications and prescriptions of ritual. Inscribed tombstones were set up over graves, which were usually placed along the chief roads leading out of a town; the most familiar example is the sacred way from Athens to Eleusis. Inscriptions commemorative of victories or other great events were erected upon the spot only in exceptional cases; more often such memorials were set up in some great religious centre such as Delphi or Olympia. But boundary stones were necessarily placed on the line which they defined.

Chief Periods and Nationalities.—The study of inscriptions supplies an important contribution to the history of many lands and peoples. In some cases, as in Egypt and Mesopotamia, it forms almost the only source of first-hand written information; in others, as in Greece and Rome, it offers a most valuable supplement and comment to what is otherwise recorded.

Both Egyptian and Mesopotamian inscriptions go back to an extremely early date; it is uncertain which is the earlier but both show, as early as 3000 B.C., a complete, organized system of writing which implies many centuries of development behind it. The Egyptian hieroglyphic script, as used in inscriptions, continued without any essential change of character until Roman times, though various cursive hieratic and demotic types were also in use. On the famous Rosetta stone in the British museum, which first gave the clue to the interpretation of Egyptian writing, hieroglyphic, demotic and Greek versions of the same decree are given side by side. Its date is 195 B.C. The Mesopotamian linear symbols developed, mainly for technical reasons, into a wedge-shaped or cuneiform system which was adopted in modified forms and applied for millennia to different languages: Sumerian, Babylonian, Assyrian, Hurrian, Hittite and Old Persian. An independent hieroglyphic system, which also developed into various linear scripts, appeared in Crete around 2000 B.C. (*see* MINOAN LINEAR SCRIPTS). The Hittite hieroglyphs date from the period of Hittite domination in northern Syria and Asia Minor, from about 1600 to 700 B.C. (*See* also HIEROGLYPHS.)

The earliest known Phoenician inscriptions date from about the 10th century B.C., and the alphabet remained in use down to the 3rd century B.C. It was modified and adopted by the Greeks at an uncertain date; the earliest Greek inscriptions are generally dated in the 8th century B.C.

In early times each Greek state had its own alphabet; but in the year 403 B.C. (the archonship of Eucleides) the Ionian alphabet, which is the one used now for Greek capital letters, was officially adopted by Athens and soon became universal in Greece. From the various Greek alphabets were derived the different local Italian types, including the Etruscan, with sundry modifications. The Roman alphabet was among these. There are a few very early Roman inscriptions. They did not become common until the 3rd century B.C.; from that time the letters took much the same forms as they preserve to the present day.

The custom of putting inscriptions in Greek and in Latin on buildings and other monuments continued through medieval times and is still customary, classical forms being frequently imitated. The latest dated inscription in the Greek Corpus records the building of a bridge in Sicily in A.D. 1121; the series of Byzantine inscriptions continues practically without interruption to the present day; and Latin retains its use as a universal language in religious, public and private inscriptions.

Methods of Dating.—It is often possible to date an inscription approximately by the style of the lettering, or even by the alphabet used. Thus at Athens the Ionic alphabet was adopted in place of the early Attic alphabet in 403 B.C. But the change was already in process in private inscriptions, and Ionic forms are sometimes found earlier, even in official documents. Inscriptions are dated in various ways, mostly by giving the name of a king, magistrate or priest. In the case of kings, they only give an approximate date, unless the year of his reign is given also. But in the case of most independent cities the date is given by the name of an annual magistrate, and thus the year is indicated precisely. At Athens, the name used was that of the Eponymous Archon and, since an almost complete list of these has been drawn up from inscriptions and other sources, this means of dating is quite satisfactory. The custom of dating by Olympiads, which is familiar from later Greek and Roman writers, was rarely used in early Greece, except in connection with athletic victories. Many inscriptions are dated from various local eras, often based upon historical events such as the foundation of a town or festival, the organization of a province or even the visit of an emperor. The number of these eras in later times, especially in Asia Minor, becomes very bewildering. In Attic decrees, and some others, it also was usual to give the day of the month.

In Greek inscriptions of the Roman period, the year of the emperor is defined by the number of his consulate or other indications or titles, as in the corresponding Latin inscriptions. In later times, the dating is commonly by indiction, *i.e.*, in terms of the 15-year tax cycle, but as this only gives the number of the year within such a period, while leaving that period undefined, such dating is very inconvenient, except for merely temporary use. In the Eastern empire the date from the creation of the world (5509 B.C.) is sometimes given; but the date of the Christian era is hardly ever used.

CONTENT

Purpose of Inscriptions.—Inscriptions may be divided roughly into two main classes: (1) those in which the inscription was subservient to the object on which it was inscribed or, at any rate, had a direct relation to that object (*e.g.*, the name of the owner or the record of dedication to a god); and (2) those in which the inscription existed for its own sake, or for the sake of the information which it recorded, the object on which it was inscribed being either made for the purpose, as a slab of marble or plate of bronze, or made use of, as in the case of a convenient wall or the surface of a rock or even a potsherd. The walls of buildings are often covered with such inscriptions, especially if they are in a conspicuous or convenient position, and so offer an obvious means of publicity.

For those accustomed to a vast mass of books, newspapers and other printed documents, it is difficult to realize the extensive use and great convenience assigned to inscriptions in ancient times. Not only were public announcements of all sorts, such as should now be made known by advertisements or posters, thus placed before the public, but all kinds of records and enactments—codes of law and political decrees; regulations for all matters, civil and religious; accounts and contracts, public and private; treaties between states; records of public and private benefactions and dedications, and all matters of administration; honours to the living and to the memory of the dead. Many of these were intended to preserve for all time the records which they contained; but others must have been of only temporary interest. It seems, therefore, the more remarkable that they should have been incised on permanent material such as bronze, marble or stone—and incised in the first instance, with a care and perfection of technique which have led to their survival to the present day, so

as to preserve invaluable evidence as to the life and institutions of the people who made them. Temporary and permanent value are thus often combined in the same inscription. For instance, an Athenian citizen, visiting the Acropolis or the market place, could satisfy himself at first hand as to treaties or decrees of the people, public accounts or state income and expenditure. In the near east and Helladic Greece vast archives of clay tablets were kept in royal palaces and temples.

Relative Inscriptions.—Inscriptions having a direct relation to the object, or representation, on which they are inscribed vary greatly in their contents. Those relating to picture or relief chronicles of the victories or exploits of kings, as in Egypt and Mesopotamia, serve as a record of the events and help to interpret the scenes. Such inscriptions are not common in Greek or Roman work; but frequently, especially in early Greek times and on vases, the names of persons and even of objects are written beside them for the purpose of identification, and sometimes a speech issues from the mouth of a figure. On the carved wooden chest of Cypselus, of about 600 B.C., hexameter verses were written, curving about among the figures and giving a description of each scene. The bases of statues and reliefs often had inscriptions cut upon them for identification and record. This was particularly the case with honorary statues and tombstones. In other cases, where there is an evident relation between the artistic representation and the inscription, the figures are subordinate and seem merely to illustrate the text, such as a treaty between Athens and Samos with a relief at its head representing the goddesses Athena and Hera clasping hands, as representatives of their respective cities. In other cases the arms or device of a city is carved on an inscription, almost like a seal on a document. In all these cases the figures and the inscription are part of a common design, whether carried out by the same hand or not. But in the case of owners' marks, or names cut on vases or other objects, or of the dedication of such objects, the inscription is not necessarily contemporary; it may indeed be misleading, as in the case, mentioned with disapproval by Cicero, of re-using old Greek statues and placing new dedicatory inscriptions on them in Roman times; for instance, one of the statues of Athenian knights of the 5th century B.C., placed at the entrance of the Acropolis, had a later inscription cut on its base to make it serve as an equestrian statue of Germanicus, probably in 18 A.D. when he visited Athens. In Egypt and Mesopotamia also it is not unusual to find the name of a later king or official cut upon an earlier work.

Independent Inscriptions.—The majority of inscriptions are of independent value and interest, the object on which they are cut being either provided for the purpose or utilized as convenient and suitable. Such inscriptions may be classified as (1) religious and (2) political and social. The distinction between the two is not always easy to draw; for in almost all ancient civilizations religion was a part of the established service of the state and was under public control, or at least was closely bound up with political administration. It follows that many inscriptions relating to religious matters take the form of political decrees or state documents, and therefore might, especially as far as form is concerned, be included in either category; but it is usually possible to classify them according to their contents and intention.

Greek Inscriptions

Religious.—*Temples.*—A temple was often a kind of religious corporation under the control of the state, and its accounts and details of administration were made public at frequent intervals, usually annually, by means of inscriptions, exhibited to public view in its precinct. Many such inscriptions have been found and they supply a great deal of information that can be obtained from no other source. Some great temples, such as that of Apollo on the island of Delos, held great amounts of property, both real and portable, the latter taking the form either of more or less precious offerings dedicated in the temple and its surrounding buildings, or of coined money. The inscriptions accordingly record gifts and acquisitions of landed property, leases and assignments, payments of rent and fines for default, loans and interest and many other business transactions suitable to a great landed proprietor or to a bank. They therefore throw much light upon the social and economic conditions of ancient life, such as are nowhere else recorded. The lists of offerings dedicated in the temple and other buildings almost recreate their appearance. These offerings are described as being on the floor, on the walls, on shelves or in cases; they consisted of vases and other objects suitable for use in the temple service; ornaments and jewels; statuettes, mostly in gold and silver; weapons and tools; coined money; and bullion, mostly melted down from old offerings. The detailed care that was taken to ensure that the full weight of melted objects was preserved, whether made into a new vessel or not, is recorded in other inscriptions. These elaborate inventories were checked and revised by each successive board of administrators, and gave the best possible security against any robbery or peculation. In addition to such general lists, there are also innumerable records of various gifts and acquisitions, whether of land and houses, or of movable property of all sorts. Buildings and repairs, sometimes by the state, sometimes by individuals, whose piety and generosity are suitably honoured, are also recorded. In form, these are often hardly to be distinguished from public works of a secular character, which must be mentioned later.

The inscriptions on or belonging to special dedications are often of great historical interest—there need only be quoted the inscription on the famous snake column from Delphi, with the list of the Greek states which took part in the Persian War, and that relating to the Roman arms dedicated by Pyrrhus of Epirus at Dodona after his victories. Most of the great temples being of immemorial sanctity, it is hardly to be expected that any records of their foundation should be found in inscriptions. But on the other hand there are many accounts of the dedication of new temples, either by states or communities or by private individuals. In almost all such cases it was necessary to obtain sanction for the foundation from the state; thus the inscription often takes the form of a decree of the people authorizing the foundation of the temple, and often giving some privileges to the founder or founders.

Officials.—Inscriptions give much information as to priests and other religious officials. There are, in the first place, lists of priests, some of them covering long periods and even going back to mythical times; there are also lists of the treasurers and administrators, who were usually lay officials appointed for the purpose either by election or by lot. The duties and privileges of priests are recorded in many inscriptions, and vary considerably from place to place. It is recorded, for instance, what portions of a victim at any sacrifice were to be received by the priest. In any important temple this must evidently have been far more than the priest or his family could consume; accordingly, it must have been sold, and so constituted a considerable source of income. Consequently a priesthood was an office well paid and much sought after; and in later Greek times, especially in Asia Minor, priesthoods were frequently sold, under proper guarantees and with due sureties as to the duties being carried out. Sometimes a fee to the priest had to be paid in cash; in some cases a priest or priestess was allowed to take up a collection on certain days. On the other hand, the duties of a priest are often recorded; he had to see to the cleaning and care of the temple and its contents, to provide flowers and garlands for decorations and to supply the regular daily service. Sacrifices on great occasions were usually provided by the state, as also were important repairs; but in some cases a priest undertook these on his own account, and was honoured accordingly—for instance, by being allowed to inscribe his name in the restored temple.

Besides priests, many other officials of various ranks were attached to temples and recorded in inscriptions. Some of these, especially those who were concerned with buildings or constructions, or with the inventories of temple treasures and the accounts of administration, were lay officials appointed by the state, as in the case of political officers. But many others had specialized sacerdotal functions; for instance, in many places there were *manteis* or prophets, often of special families with hereditary skill in divination; at Eleusis records were found of the hierophant,

the torchbearer and others who took part in the celebration of the mysteries. At Olympia, in later Greek times, was found a remarkable list of officials, viz.: three priests, three libation pourers, two prophets, three custodians (of keys), a flute player, an interpreter, a priest for the daily sacrifice, a secretary, a wine pourer, three dancers at libations, a woodman (to supply wood for the sacrifices) and a steward and cook—the last being no sinecure, in view of the numerous sacrificial feasts.

There were also many more menial offices in the service of temples which were carried out by slaves. Such slaves were often presented to the temple or acquired in some other way. There is a whole class of inscriptions, found on many sites, in which the sale of slaves to a temple or to the god of a temple is recorded. It is often difficult to know whether such slaves were intended for the service of a temple, or, on the other hand, such service was either purely formal or was not required at all, the sale to the temple being intended as fictitious, so as to enable a slave to acquire his own freedom and at the same time to secure the protection of the god in his free status.

Ritual.—The ritual appropriate to different divinities and temples varied greatly from place to place, and it was therefore necessary or desirable to set up notices in all public places of worship for the information and guidance of worshipers. The commonest and most essential act of worship was sacrifice; an example of the simplest form of prescription is to be seen in the inscription on the relief from Thasos in the Louvre: "To the Nymphs and to Apollo the leader of the Nymphs, the worshiper may, if he so choose, sacrifice a male and a female victim. It is not permissible to offer a sheep or a pig. No paean is sung. To the Graces it is not permissible to offer a goat or a pig."

It is to be noticed that this order of service contains a prohibition as well as a prescription. Such prohibitions are frequent, and often relate to the need of ceremonial purity in all worshipers entering a sacred precinct. They must, for a certain time, have abstained from certain prescribed means of pollution, varying from place to place. The officials are sometimes ordered to erect notices giving information on this point; for instance, at the precinct of Alectrona at Ialysus, it was prescribed that "no horse, ass, mule, nor any other animal with a bushy tail should enter, and that nobody should bring such animals in or wear shoes or any article produced from pigs. There is also a fine for driving in sheep." Other precincts were protected in a more general manner from any invasion or violation. It was prohibited to cut wood or to remove earth and stones or to drive any beasts into some precincts; the right of erecting booths was either restricted or denied altogether. Sometimes more detailed prescriptions are given for the whole organization of a festival; thus at Andania, in Messenia, the arrangements for the celebration of the local Eleusinia—the dress of the participants, the officials and policing—are very fully described. Similarly, in the hall of the Iobacchi, at Athens, the order of proceedings, the officers and the characters in the sacred play and various administrative details are ordered.

When there was any doubt about a ritual or procedure, divination was often resorted to, and the results of such divination were recorded in inscriptions as a guidance for the future. It was also a common practice to consult Delphi or some other oracle in doubtful or difficult cases; in such cases the exact method of procedure was sometimes recorded, as well as the response of the oracle. Forms of worship were often prescribed or recorded, especially hymns, which were sometimes inscribed together with their musical notation. The performance of songs or hymns and dances was also a matter of constant reference, especially in connection with lyrical or musical contests; the victorious band or performer often dedicated the prize in honour of the god. A special form of contest was that in dramatic performances, of which many records have survived, both from Athens and from many other parts of the Greek world. The regulation of athletic festivals and the records of victors in their contests also form a numerous class of inscriptions. As regards mysteries, though there are numerous regulations affecting the arrangement of celebrations and the conduct of those participating, there is, as was to be expected, very little concerning the actual performances.

Another interesting phase of Greek religion known mainly from inscriptions is offered by the shrines of healing. The most notable of these was the precinct of Asclepius at Epidaurus, where lists of the cures effected by Apollo and Asclepius have been found on large slabs of inscription, compiled, in all probability, from earlier documents. The cures are of the most varied kinds, ranging from painful diseases or surgical cases to a lost boy and a broken cup. The formula is the same in almost all cases: the consultant comes to Epidaurus, sleeps in the *abaton*, has dreams or sees visions and comes out whole. In later times, when such faith healing had probably become less efficacious, elaborate prescriptions of diet and hygiene are recorded.

A special form of prayer consisted of curses, which were often buried in the ground, probably with the intent to reach the infernal gods. Such curses often give the reason for their being made, usually some injury done to the author of the curse; sometimes they devoted the offender to the infernal gods.

Private Associations.—Another element in Greek religion which is known almost exclusively by means of inscriptions is to be found in the religious associations that existed in many Greek cities, apart from the organization of state religion, though sometimes recognized by it. Each association had its own regulations, which were duly recorded in inscriptions; the associations varied greatly both in purpose and in character. Many of them had a definitely religious purpose, in the worship of certain gods; sometimes an alien community was given special permission to worship its own god or gods in its own way. Other associations were more social in character and served as clubs, or as burial societies. A remarkable feature about such associations is that the lists of members of many of them include the names of women and of slaves, thus contrasting with the civic basis of established religion in Greece and anticipating a religion in which "there is neither Jew nor Greek, there is neither bond nor free, there is neither male nor female."

Political and Social.—*Codes and Regulations.*—Ancient writers state that the earliest laws of Athens were inscribed upon tablets of wood, put together in a pyramidal shape. These, owing to their material, have perished; but there are some very early codes of law preserved on stone, notably at Gortyna in Crete. There an inscription of great length is incised on the slabs of a theatre-shaped structure in 12 columns of 50 lines each; it is mainly concerned with the law of inheritance, adoption, etc. Doubtless similar inscriptions were set up in many places in Greece. An interesting series of inscriptions deals with the conditions under which colonists were sent out from various cities, and the measures that were taken to secure their rights as citizens. A bronze tablet records in some detail the arrangements of this sort made when the Locrians established a colony in Naupactus; another inscription relates to the Athenian colonization of Salamis in the 6th century B.C.

Decrees.—A large number of inscriptions are in the form of decrees of various cities and peoples, even when their subject matter suggests that they should be classified under other headings. Almost all legislative and many administrative measures took this form; often a decree prescribed how and where the inscription should be set up. The formulae and preambles of such decrees vary considerably from place to place, and from period to period. Those of Athens are by far the most exactly known, owing to the immense number that have been discovered; and they are so strictly stereotyped that they can be classified with the precision of algebraical formulae and dated, often to within a few years, by this test alone. It was usual to record the year (by the name of the Eponymous Archon), the day of the month and of the prytany (or presiding commission according to tribes), the various secretaries, the presiding officials and the proposer of the decree. It is also stated whether the resolution was passed by the senate (Boule), by the assembly of the people (Ecclesia), or by both. The circumstances or the reason of the resolution are then given, and finally the decision itself. Some other cities followed Athens in the form of their decrees, with such local variations as were required; others were more independent in their development,

and different magistracies or forms of government had various results. In the Hellenistic age and later, the forms of independent government were kept up to a great extent, though little real power remained with the people. On the other hand, it is a common thing to find letters from kings, and later from Roman emperors, inscribed and set up in public places.

Public Accounts.—It was customary to inscribe on stone all records of the receipt, custody and expenditure of public money or treasure, so that any citizen could verify for himself the safety and due control of the state in all financial matters. As in the case of temple accounts, it was usual for each temporary board of officials to render to their successors an account of their stewardship, and of the resources and treasures which they handed over. In all cases of public works the expenditure was ordered by the state, and detailed reports were drawn up and inscribed on stone at intervals while the work was being carried out. In many cases there is a detailed specification of building work which makes it possible to realize not only all the technical details and processes employed, but also the whole plan and structure of a building. A notable instance is the arsenal of Philon, which has been completely reconstructed on paper by architects from the building specification. In the case of the Erechtheum, there is not only a detailed report on the unfinished state of the building in 409 B.C., but also accounts of expenditure and payments to the workmen employed in finishing it. Similar accounts have been preserved of the building of the Parthenon, spread over 15 years; in the case of both the Parthenon and the Erechtheum, there are included the payments made to those who made the sculptures.

Naval and military expenditure is also very fully accounted for; among other information there are records of the galley slips at the different harbours, and of the ships of the Athenian navy, with their names and condition. In short, there is no department of state economy and financial administration that is not abundantly illustrated by the record of inscriptions.

Tribute Lists.—A set of records of high historical value are the tribute lists, recording the quota paid to Athens by her subject allies during the 5th century B.C. These throw much light on her relations with them at various periods. (*See* DELIAN LEAGUE.)

Ephebic Inscriptions.—An institution about which knowledge is mainly derived from inscriptions is the ephebic system at Athens (*see* EPHEBI). There are not only records of lists of ephebi and of their guardians and instructors but also decrees in honour of their services, especially in taking their due part in religious and other ceremonies, and resolutions of the ephebi themselves in honour of their officials. It is possible to trace in the inscriptions, which range over several centuries, the gradual transformation of what was originally a system of physical and military training for Athenian youths from the age of 18 to 20, with outpost and police duties. In later times there were added to the instructors in military exercises, others who gave lectures on what should now be called arts and science subjects; thus in Hellenistic and Roman times, when youths from all parts of the civilized world flocked to Athens as an intellectual centre, the ephebic system became a kind of cosmopolitan university.

Political and Commercial Agreements.—In addition to inscriptions which are concerned with the internal affairs of various cities, there are many others recording treaties or other agreements of an international character between various cities and states. These were incised on bronze or stone and set up in places of public resort in the cities concerned, or in common religious centres such as Olympia and Delphi. The simplest form of treaty is merely an alliance for a certain term of years, usually with some penalty for any breach of the conditions. Often an oath was prescribed, to be taken by representatives on each side; it was also not unusual to appeal to the god in whose temple the treaty was exhibited. In other cases a list of gods by whom the two parties must swear was prescribed. Commercial clauses were sometimes added to treaties of alliance, and commercial treaties are also found, agreeing as to the export and import of merchandise and other things. In later days, especially in the time of the Hellenistic kings, treaties tended to become more complicated and detailed in their provisions.

Another series of records of great historical interest is concerned with arbitration between various states on various questions, mainly concerned with frontiers. In cases of dispute it was not uncommon for the two disputants to appoint a third party as arbitrator. Sometimes this third party was another state, sometimes a specified number of individuals. Thus, in a frontier dispute between Corinth and Epidaurus, 151 citizens of Megara were appointed by name to arbitrate, and when the decision was disputed, 31 from among them revised or confirmed it. In all such cases it was the custom for a full record to be preserved on stone and set up in the places concerned. In this case the initiative in referring the matter to arbitration came from the Achaean league.

Proxenia Decrees.—A very large class of inscriptions deals with the institution of *proxenia*. According to this, a citizen of any state might be appointed *proxenos* of another state; his duties would then be to offer help and hospitality to any citizen of that other state who might be visiting his city, and to assist him in any dispute or in securing his legal rights. The office has been compared to the modern appointment of consuls, with the essential difference that the *proxenos* was always a citizen of the state in which he resided, not of that whose citizens and interests he assisted. The decrees upon this matter frequently record the appointment of a *proxenos* and the conferring on him of certain benefits and privileges in return for his services; they also contain resolutions of thanks from the city served by the *proxenos* and record honours consequently conferred upon him.

Individual Honours.—This class of inscription is, in form, not unlike the last, except that the honours recorded were given for all sorts of services, private and public, to the state and to individuals. A frequent addition is an invitation to dine in the Prytaneum at Athens. Some were inscribed on the bases of statues set up to the recipient. In early times these inscriptions were usually brief and simple. The bust of Pericles on the Acropolis held nothing but the names of Pericles himself and of the sculptor Cresilas. Later it became usual to give, in some detail, the reasons for the honours awarded; in Hellenistic and Roman times these became more and more detailed and fulsomely laudatory.

Artists' Signatures.—These inscriptions are of special interest for the light they throw upon the history of art. The artist's name was usually carved upon the base or pedestal of a statue, especially in earlier times, and consequently was easily separated from it if the statue was carried off or destroyed. An instance in which both statue and pedestal are preserved is the Victory, signed on its pedestal by Paeonius at Olympia. Occasionally, and more frequently in later times, the artist's signature was carved upon some portion of the statue itself. But in later copies of well-known works it has to be considered whether the name is that of the original artist or of the copyist who reproduced his work.

A special class of artists' signatures is offered by the names signed by Attic vase painters and others upon their vases. These have been made the basis of a minute historical and stylistic study of the work of these painters and unsigned vases also have been grouped with the signed ones, so as to make an exact and detailed record of this branch of Greek artistic production.

Historical Records.—The great majority of these fall into one of the classes already referred to. But there are some instances in which an inscription was set up merely as a record, *e.g.*, a list of athletic or other contest victories. The most famous historical record is the autobiographical account of the deeds and administration of Augustus, which was reproduced and set up in many places; it is generally known as the Monumentum Ancyranum because the most complete copy of it was found at Ancyra. The Marmor Parium at Oxford, found in Paros, is a chronological record of Greek history, probably made for educational purposes and valuable for the traditional dates it gives of events from the earliest times.

Tombs.—This is by far the most numerous class of inscriptions, both Greek and Latin. In early Athens often no record was left beyond the name of the deceased, the name of his father and his deme. Sometimes a word or two of conventional praise was added, such as "a good and wise man." Occasionally the circum-

stances of death were alluded to, especially if it took place in battle or at sea. Such epitaphs were frequently in metrical form, usually either hexameters or elegiacs. Many of them have been collected and they form an interesting addition to the Greek anthology. In later times it became usual to give more elaborate praise of the deceased; but this was hardly ever so detailed as on more modern tombstones. The age and other facts about the deceased were occasionally given on Greek tombstones, but not nearly so often as on Latin ones, which offer valuable statistical information in this respect.

Latin Inscriptions

Latin inscriptions may be classified on much the same lines as Greek; but certain broad distinctions may be drawn at the outset. They are generally more standardized in form and in content, not only in Rome and Italy but also throughout the provinces of the Roman empire. One of the chief difficulties in deciphering Latin inscriptions lies in the extensive use of initials and abbreviations. These are of great number and variety, and while some of them can be easily interpreted as belonging to well-known formulae, others offer considerable difficulty, especially to the inexperienced student. A mere list of such initials and abbreviations occupies 68 pages in R. Cagnat's *Cours d'epigraphie latine*. Often the same initial may have many different meanings according to the context. Some common formulae such as V.S.L.M. (*votum solvit libens merito*, "according to justice he discharges his vow willingly"), or H.M.H.N.S. (*hoc monumentum heredem non sequetur*, "this monument is not to pass to the heir") offer little difficulty, but there are many which are not so obvious and leave room for conjecture. Often the only way to determine the meaning is to search through a list of initials, such as those given by Cagnat, until a formula is found which fits the context.

Most of what has been said about Greek inscriptions applies to Roman also. The commonest materials in this case also are stone, marble and bronze; but a more extensive use is made of stamped bricks and tiles, which are often of historical value as identifying and dating a building or other construction. The same applies to leaden water pipes which frequently bear dates and names of officials. Terra-cotta lamps also frequently have their makers' names and other information stamped upon them. Arms, and especially shields, sometimes bear the name and corps of their owners. Leaden disks were also used to serve the same purpose as modern identification disks. Inscriptions are also found on sling bullets—Roman as well as Greek; there are also numerous classes of *tesserae*, or tickets of admission to theatres or other shows.

As regards the contents of inscriptions, there must evidently be a considerable difference between the records of a number of independent city states and an empire including almost all the civilized world; but municipalities maintained many of their independent traditions in Roman times, and consequently their inscriptions often follow the old formulas.

The classification of Roman inscriptions may, therefore, follow the same lines as the Greek, except that certain categories are absent and that some others, not found in Greek, are of considerable importance.

Religious.—*Temple Dedications.*—These are very numerous; and the custom of placing the name of the dedicator in a conspicuous place on the building was prevalent, especially in the case of dedications by emperors or officials, or by public bodies. Restoration or repair was often recorded in the same manner. In the case of small objects the dedication is usually simple in form; it usually contains the name of the god or other recipient and of the donor, and a common formula is D.D. (*dedit, donavit*, "he gave," "he has given"), often with additions such as L.M. (*libens merito*, "willingly according to justice"). Such dedications are often the result of a vow, and V.S. (*votum solvit*, "he discharges his vow") is therefore often added. Bequests made under the wills of rich citizens are frequently recorded by inscriptions; these might either be for religious or for social purposes.

Officials.—A priesthood was frequently a political office and consequently is mentioned along with political honours in the list of a man's distinctions. The priesthoods that a man had held are usually mentioned first in inscriptions, before his civil offices and distinctions. Religious offices, as well as civil, were restricted to certain classes, the highest to those of senatorial rank, the next to those of equestrian status; many minor offices, both in Rome and in the provinces, are enumerated in their due order.

Regulations.—Among the most interesting of these is the ancient song and accompanying dance performed by the priests known as the Arval brothers. This is, however, not in the form of a ritual prescription, but a detailed record of the due performance of the rite. An important class of documents is the series of calendars that have been found in Rome and in various Italian towns. These gave notice of religious festivals and anniversaries, and also of the days available for various purposes. The bronze tablets from Iguvium contain extensive ritual instructions in the Umbrian dialect for a cult association known as the Atiedian brethren.

Colleges.—The various colleges for religious purposes were very numerous. Many of them, both in Rome and Italy and in provincial municipalities, were of the nature of priesthoods. Some were regarded as offices of high distinction and were open only to men of senatorial rank; among these were the Augurs, the Fetiales, the Salii and, in imperial times, the Sodales Divorum Augustorum. The records of these colleges sometimes give no information beyond the names of members, but these are often of considerable interest. Haruspices and Luperci were of equestrian rank.

Political and Social.—*Codes and Regulations.*—Information as to these is not drawn mainly from inscriptions and, therefore, they need not be considered here. On the other hand, the word *lex* (law) is usually applied to all decrees of the senate or other bodies, whether of legislative or of administrative character. It is best, therefore, to consider all together under the heading of public decrees.

Laws and Decrees.—A certain number of these dating from republican times are of considerable interest. One of the earliest relates to the prohibition of bacchanalian orgies in Italy; it takes the form of a message from the magistrates, stating the authority on which they acted. Laws all follow a fixed formula, according to the body which passed them. First there is a statement that the legislative body was consulted by the appropriate magistrate in due form; then follows the text of the law; and finally the sanction, the statement that the law was passed. In decrees of the senate the formula differs somewhat. They begin with a preamble giving the names of the consulting magistrates, the place and conditions of the meeting; then comes the subject submitted for decision, ending with the formula Q.D.E.R.F.P. (*quid de ea re fieri placeret*, "what does the senate determine to be done concerning this matter?"); then comes the decision of the senate, opening with D.E.R.I.C. (*de ea re ita censuerunt*, "concerning this matter they have resolved thus"). C is added at the end, to indicate that the decree was passed. In imperial times the emperor sometimes addressed a speech to the senate, advising them to pass certain resolutions; or, especially in later times, he would give orders or instructions directly, either on his own initiative or in response to questions or references. The number and variety of such orders is such that no classification of them can be given here.

One of the most famous is the edict of Diocletian, fixing the prices of all commodities. Copies of this in Greek as well as in Latin have been found in various parts of the Roman empire.

Building Records.—A very large number of inscriptions record the building or repair of public buildings by private individuals, by Roman or provincial magistrates and by emperors. In addition to the dedication of temples, inscriptions recording the construction of aqueducts, roads, especially on milestones, baths, basilicas, porticos and many other works of public utility are found. In early inscriptions often nothing was given but the name of the person who built or restored the edifice and a statement that he had done so. But later it was usual to give more detail as to the motive of the building, the name of the emperor or a magis-

trate giving the date, the authority for the building and the names and distinctions of the builders; then follows a description of the building, the source of the expenditure (*e.g.*, S.P.-*sua pecunia*, "his money") and finally the appropriate verb for the work done, whether building, restoring, enlarging or otherwise improving. Other details are sometimes added, such as the name of the man under whose direction the work was done.

Military Documents.—These vary greatly in content, and are among the most important documents concerning the administration of the Roman empire. "They are numerous and of all sorts—tombstones of every degree, lists of soldiers' burial clubs, certificates of discharge from service, schedules of time-expired men, dedications of altars, records of building or of engineering works accomplished. The facts directly commemorated are rarely important." But when the information from hundreds of such inscriptions is collected together, "you can trace the whole policy of the imperial Government in the matter of recruiting, to what extent and till what date legionaries were raised in Italy; what contingents for various branches of the service were drawn from the provinces, and which provinces provided most; how far provincials garrisoned their own countries, and which of them, like the British recruits, were sent as a measure of precaution to serve elsewhere; or, finally, at what epoch the empire grew weak enough to require the enlistment of barbarians from beyond its frontiers." (F. Haverfield, *Authority and Archaeology*, p. 314.)

Treaties and Agreements.—There were many treaties between Rome and other states in republican times; but as a rule, knowledge of these does not derive from inscriptions, which are very rare in this earlier period. In imperial times, to which most Latin inscriptions belong, international relations were subject to the universal domination of Rome, and consequently the documents relating to them are concerned with reference to the central authority, and often take the form of orders from the emperor.

Proxeny.—This custom belonged to Greece. What most nearly corresponded to it in Roman times was the adoption by a city or a state of some distinguished Roman as its patron. The relation was then recorded, usually on a bronze tablet placed in some conspicuous position in the town concerned. The patron probably also kept a copy in his house, or had a portable tablet which would ensure his recognition and reception.

Individual Honours.—Honorary inscriptions were extremely common in all parts of the Roman world. Sometimes they were placed on the bases of statues, sometimes in documents set up to record some particular benefaction or the construction of some public work. The offices held by and the distinctions conferred upon the person commemorated are enumerated in a regularly established order (*cursus honorum*, "order of honours"), either beginning with the lower and proceeding step by step to the higher, or in reverse order with the highest first. Religious and priestly offices are usually mentioned before civil and political ones. These might be exercised either in Rome itself, or in the various municipalities of the empire.

There was also a distinction drawn between offices that might be held only by persons of senatorial rank, those that were assigned to persons of equestrian rank and those of a less distinguished kind. It follows that when only a portion of an inscription has been found, it is often possible to restore the whole in accordance with the accepted order.

Artists' Signatures.—When these are attached to statues it is sometimes doubtful whether the name is that of the man who actually made the statue or of the master whose work it reproduces. Thus there are two well-known copies of a statue of Hercules by Lysippus, of which one is said to be the work of Lysippus and the other states that it was made by Glycon. Another kind of artist's or artificer's signature that was commoner in Roman times is to be found in the signatures of potters upon lamps and various kinds of vessels; they are usually impressed on the mold and stand out in relief on the terra cotta or other material. These are of interest for the information they give as to the commercial spread of various kinds of handicrafts and the conditions under which they were manufactured.

Historical Records.—Many of these inscriptions might well be assigned to one of the categories already considered. But there are some which were made expressly to commemorate an important event or to preserve a record. Among the most interesting is the inscription of the Columna Rostrata in Rome, which records the great naval victory of Duilius over the Carthaginians; this, however, is not the original, but a later and somewhat modified version. A document of high importance is a summary of the life and achievements of Augustus, already mentioned, known as the Monumentum Ancyranum. The various sets of Fasti constituted a record of the names of consuls and other magistrates or high officials, and also of the triumphs accorded to conquering generals.

Tombs.—These are probably the most numerous of all classes of inscriptions. Though many of them are of no great individual interest, they convey, when taken collectively, much valuable information as to the distribution and transference of population, as to trades and professions, as to health and longevity and as to many other conditions of ancient life. The most interesting early series is that on the tombs of the Scipios at Rome, recording, mostly in Saturnian metre, the exploits and distinctions of the various members of that family.

About the end of the republic and the beginning of the empire, it became customary to head a tombstone with the letters D.M. or D.M.S. (*dis manibus sacrum*, "sacred to the shades of the gods"), thus consecrating the tomb to the deceased as having become members of the body of ghosts or spirits of the dead. These are followed by the name of the deceased, usually with his father's name and his tribe, by his honours and distinctions and sometimes by a record of his age. The inscription often concludes with H.I. (*hic iacet*, "here lies") or some similar formula, and also, frequently, with a statement of boundaries and a prohibition of violation or further use—for instance, the formula mentioned above, H.M.H.N.S.

The person who erected the monument and his relation to the deceased are often stated; or if a man has prepared the tomb in his lifetime, this also may be stated, V.S.F. (*vivus sibi fecit*, "while living he made this for himself"). But it is obvious that there is an immense variety in the information that either a man himself or his friends might wish to record.

Milestones and Boundaries.—Milestones (*miliaria*) have already been referred to, and may be regarded as records of the building of roads. Boundary stones (*termini*) are frequently found, both of public and private property. A well-known instance is offered by those set up by the commissioners called "III. viri A.I.A." (*agris iudicandis adsignandis*, "for assigning boundaries of farms") in the time of the Gracchi.

INSECT, any member of the class Insecta (or Hexapoda), the largest class of the largest animal phylum, Arthropoda (*q.v.*). Like all arthropods, the insects have segmented bodies, jointed legs and, when present, external skeletons (exoskeletons). However, insects are distinguished from other arthropods by having the body divided into three major regions, which appear to be deeply incised (hence the term "insect" from the Latin meaning "cut in"). These three regions are: (1) the head, which bears the mouth parts, eyes and a pair of antennae; (2) the thorax, which usually has three pairs of legs (hence "Hexapoda," the former class name) and often one or two pairs of wings; and (3) the many-segmented abdomen, which contains the digestive, excretory and reproductive organs.

Popularly "insect" brings to mind the familiar pests or disease carriers, from bedbugs, houseflies and clothes moths to Japanese beetles and aphids; the annoyers, such as mosquitoes, fleas, horseflies and hornets; and the conspicuous butterflies and moths. The pest species are actually in the minority, most insects being beneficial from man's viewpoint; they pollinate plants, produce useful substances, control pest insects, act as scavengers and serve as food for other animals (see *Importance of Insects*, below).

Insects as organisms—their origin and evolution, metamorphosis and development, anatomy and physiology, habits and behaviour, classification—and the ways in which they are useful or injurious to man are discussed below. Further information on their structure and habits is presented in articles on particular insects and on various insect orders. The science that is concerned with insects from the broad biological and applied aspects is considered under the title Entomology.

The following topics are discussed here:

I. Introduction
  1. Size Range
  2. Distribution
  3. Diversity
  4. Abundance
II. Structure and Function
  1. External Features
  2. Senses and Communication
  3. Musculature and Locomotion
  4. Feeding and Digestion
  5. Nutrition and Metabolism
  6. Respiration
  7. Blood and Associated Tissues
  8. Light Production
  9. Excretion
  10. Reproduction
  11. Nervous System
  12. Behaviour
III. Life History
  1. Development
  2. Growth and Molting
  3. Metamorphosis
IV. Importance of Insects
  A. Beneficial Insects
    1. Pollination
    2. Balance of Nature
    3. Useful Products
    4. Scientific and Aesthetic Value
  B. Harmful Insects
    1. Effects on Man's Health
    2. Attacks on Domestic and Game Animals
    3. Injury to Plants
    4. Damage to Stored and Manufactured Goods
V. Origin and Evolution of Insects
  1. Insect Ancestors
  2. The First Insects
  3. Evolution of Wings
  4. Evolution of Complete Metamorphosis
VI. Classification
  A. Apterygota (Ametabola)
    1. Collembola (Springtails)
    2. Protura (Proturans or Telsontails)
    3. Diplura (Diplurans or Twintails)
    4. Thysanura (Bristletails, Silverfish, Etc.)
  B. Pterygota (Prometabola)
    Ephemeroptera (May Flies)
  C. Pterygota (Hemimetabola)
    1. Odonata (Dragonflies, Damsel Flies)
    2. Blattaria (Cockroaches)
    3. Mantodea (Mantids)
    4. Phasmida (Stick Insects)
    5. Isoptera (Termites)
    6. Dermaptera (Earwigs)
    7. Orthoptera (Grasshoppers, Crickets, Katydids)
    8. Embioptera (Embiids or Web Spinners)
    9. Plecoptera (Stone Flies)
    10. Zoraptera (Zorapterans)
    11. Psocoptera or Corrodentia (Book and Bark Lice)
    12. Mallophaga (Biting Lice)
    13. Anoplura (Sucking Lice)
    14. Thysanoptera (Thrips)
    15. Hemiptera (True Bugs, Etc.)
  D. Pterygota (Holometabola)
    1. Coleoptera (Beetles, Weevils)
    2. Strepsiptera (Twisted-Wing Insects)
    3. Megaloptera (Dobson Flies, Alder Flies)
    4. Neuroptera (Ant Lions, Lacewings, Mantispids, Etc.)
    5. Raphidioidea (Snake Flies)
    6. Mecoptera (Scorpion Flies)
    7. Trichoptera (Caddis Flies)
    8. Lepidoptera (Butterflies, Moths)
    9. Diptera (True Flies)
    10. Siphonaptera (Fleas)
    11. Hymenoptera (Ants, Bees, Wasps, Etc.)

I. INTRODUCTION

In numbers of species, in the vast numbers of individuals and in the great adaptability, wide distribution and persistence of the group as a whole, insects are perhaps the most eminently successful of all animals. They dominate the present-day land fauna; about 850,000 species have been described, representing about 80% of known animal life, yet entomologists estimate the actual number of living species as being in excess of 2,000,000. The most numerous in species are the orders Coleoptera (beetles), Lepidoptera (butterflies and moths), Hymenoptera (ants, bees, wasps, etc.) and Diptera (true flies).

1. Size Range.—The majority of insects are small, being less than $\frac{1}{4}$ in. long. The size range, however, is wide. Some are microscopic, as certain of the feather-winged beetles (family Ptiliidae), barely $\frac{1}{100}$th of an inch long; while some of the tropical forms attain considerable size, being measured in several inches, as the African goliath beetles, certain Australian stick insects and some Asian and South American moths.

2. Distribution.—Insects are adapted to every land and fresh water habitat where food is available, from deserts to lush jungles, from glacial fields and swift-running, cold mountain streams to stagnant, lowland ponds and hot springs. Many live in brackish water up to one-tenth the density of sea water, a few in sea water and some fly larvae can live in pools of crude petroleum where they eat other insects that fall in.

3. Diversity.—In many species sexual dimorphism (difference in body structure between the sexes) is pronounced, and knowledge of one sex may give little clue as to the appearance of the other sex. In some, as the twisted-wing insects (Strepsiptera), the female is a mere inactive bag of eggs, while the male is winged and one of the most active insects known. Modes of reproduction are very diverse. Parthenogenesis (reproduction without fertilization) is common in some insects (certain wasps, bees, aphids) and reproductive capacity is generally high (ants, termites, aphids, flies). Some insects, as the May flies, feed only in the larval stage and go without food as adults. Among the social insects the queen ants and queen termites live for many years (15–50), while some adult May flies live less than two hours.

Some insects advertise their presence to the other sex by flashing lights, and many imitate other insects in colour and form and thus avoid or minimize attack by predators that feed by day and find their prey visually, as birds, lizards, other insects, etc.

Behaviour is equally diverse, from the almost inanimate parasitic forms where the larva lies in the nutrient blood stream of its host and feeds by absorption, to dragonflies that pursue victims in the air, tiger beetles that outrun prey on the land and dytiscid beetles that outswim prey in the water.

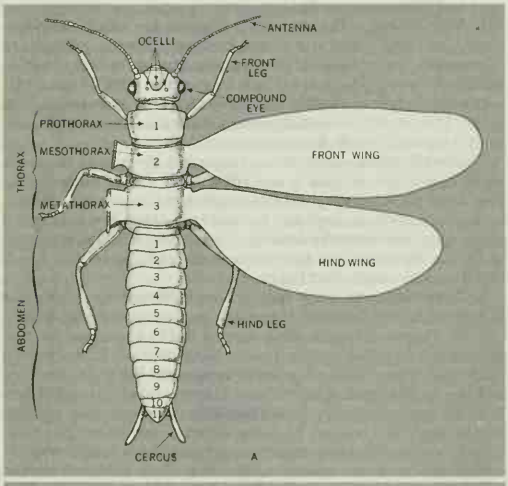
In some cases the adult insects make elaborate preparations for the young; in others the mother defends or feeds her young; and in still others there are complex insect societies, which, in the case of tropical termites and ants, may reach populations of millions of inhabitants.

4. Abundance.—No scientist familiar with insects has attempted to estimate individual numbers beyond areas of a few acres or a few square miles in extent. Figures soon become so large as to be incomprehensible. The large populations and great variety of insects are related to their small size, high rates of reproduction and abundance of suitable food supplies. Insects abound in the tropics, both in numbers of different kinds and in numbers of individuals.

A commonly used method in teaching entomology is to count the insects in and on a square yard of rich moist soil. Including the young and adults of all forms from microscopic young Collembola to all large adults, 500 are easily found and 2,000 are not unusual in samples of soil in the north temperate zone. This is roughly 4,000,000 insects on one moist acre. The untrained observer walking through such an area would probably notice only an occasional butterfly, bumblebee or large beetle, supergiants among insects. Only a few thousand species touch man's living seriously enough to require control measures—those that attack his crops, herds and products, and those that carry disease. However, when they do appear as enemies of man, they can build up populations with speed and attack in incredible numbers. In northern regions the few houseflies that winter over are rare insects, but in August their descendents occur in great numbers. Thus man moves about in a world of insects but is virtually unconscious of their vast numbers. (C. H. Ky.; X.)

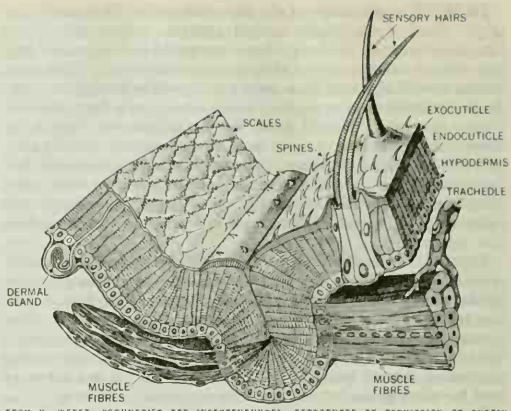
II. STRUCTURE AND FUNCTION

Insects share with other arthropods a number of structural features, including the possession of a segmented body, an external skeleton, and paired, segmented appendages, some of which are usually specialized for walking, eating, egg-laying or other particular functions.



(A) FROM H. H. ROSS, "A TEXTBOOK OF ENTYMOLOGY"; REPRODUCED BY PERMISSION OF JOHN WILEY & SONS, INC., (B) FROM H. WEBER, "GRUNDRISS DER INSEKTENKUNDE", REPRODUCED BY PERMISSION OF GUSTAV FISCHER VERLAG

FIG. 1.—MAJOR BODY PARTS OF A GENERALIZED INSECT: (A) VIEW FROM ABOVE WITH SEGMENTS NUMBERED; (B) EXTERIOR FEATURES OF MALE. WINGS NOT SHOWN; MALE ORGANS SHOWN THROUGH BODY WALL



FROM H. WEBER, "GRUNDRISS DER INSEKTENKUNDE"; REPRODUCED BY PERMISSION OF GUSTAV FISCHER VERLAG

FIG. 2.—BODY COVERING SHOWING RELATION OF CUTICLE TO OTHER FEATURES

1. External Features.—*Body Covering.*—The insect body is covered with a cuticular exoskeleton consisting chiefly of a chitin-containing substance somewhat resembling the cellulose of plants. It is secreted by a layer of epidermal cells, the hypodermis. The innermost layer (endocuticle) is colourless, tough and elastic, the outermost (exocuticle) rigid and amber-coloured. The entire cuticle is pierced by ducts of dermal glands that pour out protective secretions over the surface. Hairs and scales of various types, some of which constitute sense organs, articulate with the cuticle. The colour and pattern of an insect's body may be located either in the cuticle itself or in the hairs, scales or dust that may cover the cuticle. The colours may be produced by pigments or by optical interference of light scattered by minute striations of the surface. Black or brown colouring is generally a result of melanin pigments deposited in the exocuticle. (*See* SKELETON, INVERTEBRATE.)

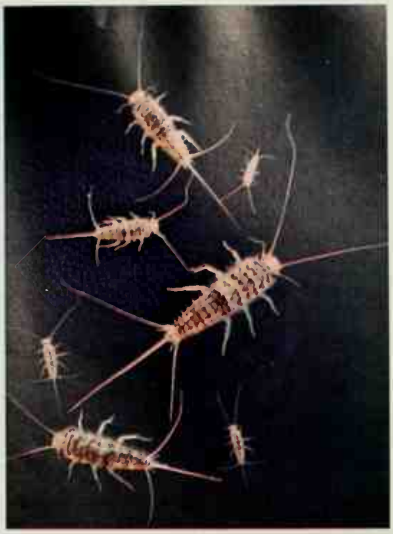
Head.—A number of fused segments form the head capsule. Attached to this capsule are the eyes and various appendages, including the antennae, which bear a variety of sense organs, and the highly modified mouth parts.

Thorax.—Three segments compose the thorax: the prothorax, mesothorax and metathorax. Usually each segment bears a pair of legs, each leg articulating with thoracic plates (sclerites), and consisting typically of a basal coxa, trochanter, femur, tibia and tarsus. In most flying insects the meso- and metathorax each bears a pair of wings, although the second pair may be reduced in size or lost, as in the true flies. The wings are traversed by veins that subdivide them into cells, the veins being stronger and more concentrated near the anterior margin. In some instances the first pair of wings is modified to form covers or sheaths (elytra) for the hind wings, as in beetles and grasshoppers. In grasshoppers the elytra fulfil a double function, as wings in flight and as covers at rest. In beetles the elytra are rigid, and in flight are held up at an angle, acting as fixed lifting surfaces.

Abdomen.—The abdomen typically consists of eleven segments, although not more than ten are visible (and in adults usually fewer) as a result of telescoping and modification into copulatory structures. In ants, bees and wasps the first abdominal segment is fused with the thorax and is termed a propodeum. Most exposed segments are typically simple, consisting of a dorsal plate (tergum), a ventral plate (sternum), and a lateral (pleural) membrane that connects them. Within the abdomen are enclosed the digestive, reproductive and excretory organs.

The complex of external structures used in copulation or egg

Dragonfly, order Odonata. Dragonflies are found throughout the world, nearly everywhere there is fresh water. This species was photographed in central Africa



Firebrats, order Thysanura. Wingless insects, in some species eyeless; firebrats are household pests

Stone fly, order Plecoptera. Medium-sized to large insect with well-developed eyes and wings. The nymphs are aquatic

May fly, order Ephemeroptera. Another flying insect found near bodies of fresh water where eggs are laid and nymphs mature

Termites, order Isoptera. Portrait of three of the castes of a *Reticulitermes* species: winged individuals are kings and queens, large yellow-headed individuals are soldiers, others are workers

REPRESENTATIVES OF INSECT ORDERS

PHOTOGRAPHS (TOP LEFT, CENTRE LEFT, BOTTOM LEFT, BOTTOM RIGHT) E. S. ROSS, (TOP RIGHT) ROMAN VISHNIAC—PUBLIX

INSECT

Brown lacewing, order Neuroptera. Soft-bodied insect with extremely elaborate venation of its large wings. Larvae are beneficial to man as aphid eaters

Earwig, order Dermaptera. A hard-bodied insect characterized by a pair of "forceps" (cerci) at the end of its abdomen

Paraphagadochir trachelia, a web spinner, order Embioptera. A social insect that lines its subterranean tunnels with silk produced from glands in its front tarsi (leg segments)

Snake fly, order Raphidiodea (considered by some a superfamily of Neuroptera). Photograph shows the long, slender ovipositor of a female as she rests on a plant stem covered with aphids

Stylops, order Strepsiptera. Twisted wing flies, a small, parasitic order. This unusual photograph shows a male in the act of fecundating a female that lives within the abdomen of a bee (note wings at top centre) that is feeding on a flower

REPRESENTATIVES OF INSECT ORDERS

PHOTOGRAPHS, E. S. ROSS

Horsefly, *Tabanus* species, order Diptera. Colour patterns of the compound eyes are used in identifying species of *Tabanus*. Houseflies and mosquitoes are also members of this order

A velvet ant, a mutillid wasp, the female of which is wingless and antlike, order Hymenoptera. This is the great order of social insects, including bees and ants. Velvet ants are parasites on other insects

Bush katydid, *Microcentrum rhombifolium*, order Orthoptera. The leaflike colour, shape and pattern of venation serve to camouflage the katydid from predators

Long-horned meadow grasshopper, *Orchelimum* species, another member of the Orthoptera, related to the katydids and crickets

Cockroach, order Blattaria (considered by some a family of Orthoptera). Flattened, quick-running scavengers, some species have become household pests. Most are tropical, such as this one from Peru

Close-up of the head of a queen bald-faced hornet (*Vespula maculata*), order Hymenoptera. This wasp is related to the common yellow jacket

REPRESENTATIVES OF INSECT ORDERS

PHOTOGRAPHS, (TOP LEFT, TOP RIGHT, CENTRE LEFT, BOTTOM LEFT) JOHN H. GERARD, (CENTRE RIGHT, BOTTOM RIGHT) E. S. ROSS

INSECT

Nymphs of the milkweed bug, a member of the chinch bug family, Lygaeidae, pests that attack many cereal crops and grains

Stink bug, family Pentatomidae, protected by its nauseous odour and taste

Triatoma species, a reduviid or assassin bug. This one is a household invader and a disease carrier that bites man

Leafhopper, a plant-sucking insect of the family Cicadellidae. Many species are destructive to the trees, shrubs and flowers upon which they feed

Cicada, *Tibicen* species, the familiar song-producing insect of the summer. The skin case left after its final molt may often be seen attached to the bark of a tree

Another reduviid bug shown emerging from its final molt to its adult stage

A shield-backed bug (family Scutellaridae) of central Africa. A plant-eating insect related to the stink bugs

HEMIPTERA: THE TRUE BUGS AND THEIR RELATIVES

PHOTOGRAPHS, (TOP LEFT) JOHN H. GERARD, (TOP CENTRE) ROMAN VISHNIAC—PUBLIX, (TOP RIGHT, CENTRE RIGHT—2, BOTTOM RIGHT) E. S. ROSS, (BOTTOM LEFT) D. DWIGHT DAVIS

Caterpillar of the cynthia moth. *See* picture and caption at right

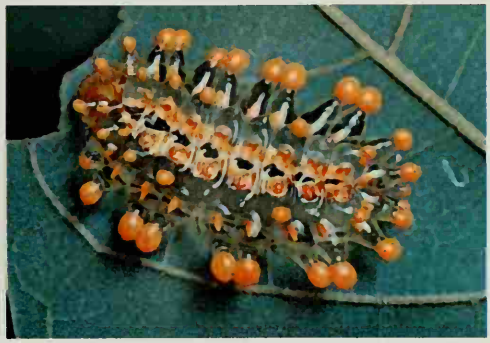
Larva of *Charaxes* species (family Nymphalidae), a large African butterfly

Cynthia moth, *Samia cynthia*, family Saturniidae, resting on a flower just after emerging from its cocoon. The wings have not yet fully opened

Red caterpillar of Peru. The hairs on this larva are poisonous

Caterpillar of the polyphemus moth (*Antheraea polyphemus*)

Measuring worm of the Congo. This is the larval stage of one of the geometrid moths, second largest family of the Lepidoptera



Exotic larva of a Peruvian lepidopteran

LEPIDOPTERA: BUTTERFLIES AND MOTHS

PHOTOGRAPHS (TOP LEFT, CENTRE RIGHT) JOHN H. GERARD; (TOP RIGHT) ROMAN VISHNIAC—PUBLIX, (OTHERS) E. S. ROSS

INSECT

The ivory-marked beetle (*Eburea quadrigeminata*), a long-horned wood-boring beetle (family Cerambycidae)

Six-spotted tiger beetle (*Cicindela sexguttata*) showing metallic coloration that is typical of many cicindelids

Tumblebugs (*Canthon laevis*) rolling a ball of dung. After a site has been selected, eggs are laid in the ball of dung and it is buried

Eyed elater (*Alaus oculatus*), a click beetle (family Elateridae)

Stag beetle (*Pseudolucanus capreolus*), a male showing the greatly enlarged mandibles that resemble the antlers of a stag

Striped blister beetle (*Epicauta vittata*) shown on a tomato, one of the crop plants on which it feeds

COLEOPTERA: BEETLES

PHOTOGRAPHS JOHN H. GERARD

Western spotted cucumber beetle (*Diabrotica undecimpunctata*), a pest which destroys cucumbers by eating and by acting as a disease carrier

White grub, the larva of the June beetle or June bug, *Phyllophaga* species

Colorado potato beetle (*Leptinotarsa decemlineata*), a serious crop pest

Fuller rose weevil (*Pantomorus godmani*), a flightless snout beetle of the western U.S., that attacks fruit trees as well as roses

The round-headed apple borer, *Saperda candida* (family Cerambycidae) shown above its emergence hole in a branch

Another cerambycid beetle, the cottonwood borer (*Plectrodera scalator*), photographed on a day lily

A Peruvian cassid or tortoise beetle, family Chrysomelidae. The brilliant metallic colours of these beetles disappear when they die

A ground beetle *Galerita bicolor*, a North American member of the large family Carabidae

COLEOPTERA: BEETLES

PHOTOGRAPHS (TOP LEFT, TOP CENTRE LOWER, TOP RIGHT, BOTTOM LEFT) E. S. ROSS, (TOP CENTRE UPPER, CENTRE LEFT, BOTTOM RIGHT) O. DWIGHT DAVIS, (CENTRE RIGHT) JOHN H. GERARD

INSECT

Aggregation of monarch butterflies (*Danaus plexippus*) resting during a migratory flight. The monarch follows a regular seasonal migration and return flight

Bee fly (family Bombyliidae) hovering as it drops its eggs into the entrance of the burrow of a ground nesting bee

Larva of a green lacewing, family Chrysopidae, carrying "trash"—the remains of victims—on its back as it forages

A rare example of nonhuman use of a "tool": a sphecid wasp tamping dirt into its burrow by means of a tiny stone held in its mandibles

A cricket singing in front of the entrance to its nest. The sound is made by raising the wings up over the back and rubbing them together

Female mantis assuming a frightening pose to ward off attack on her eggs, the white mass on which she is standing

INSECT HABITS

PHOTOGRAPHS, (TOP LEFT) D. DWIGHT DAVIS, (OTHERS) E. S. ROSS

Nest building by tailor ants (*Oecophylla species*) of Angola. Ant at left is holding a larva and squeezing it. As larva secretes silk, second ant uses it to weave leaves together. *See* below

Group of tailor ants pulling leaves together in preparation for permanent attachment by sewing with larval silk

Formica ants tending aphids. The smaller insects are "milked" by ants for a sweet "honeydew" they secrete. In return, the ants carry the aphids to choice feeding grounds and may take them into their own nests during the winter

Completed nest of the tailor ant (*see* pictures above) showing leaves gathered together and sewn around the twig of a tree. Nests may be made more than 100 ft. above the ground in tropical trees

TWO HIGHLY ORGANIZED ACTIVITIES OF THE ANTS

PHOTOGRAPHS: E. S. ROSS

INSECT

Aphids (at right) sucking the juices from a plant while an aphid lion (left), the larva of a golden-eyed lacewing, attacks an aphid

Hawk wasp stinging a large spider. The wasp carries the paralyzed spider to a burrow and deposits eggs on it

Aedes mosquito feeding on man. Note abdomen swollen with blood. Only the females are bloodsuckers

Damselfly (order Odonata) eating an insect held in its mandibles while mites (red spots) bite the damselfly. Mites are arachnids, members of the same phylum (Arthropoda) as insects

Blues (lycaenid butterflies) drinking at a mud hole. Note extended proboscises

Robber fly (family Asilidae) feeding upon a grasshopper. Prey is held by the strong legs of the fly while it uses its beak to puncture the integument of its victim

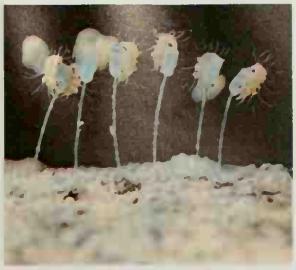
Aulicus, a checkered beetle (family Cleridae), feeding upon an insect larva

INSECTS FEEDING

PHOTOGRAPHS (TOP LEFT) ROMAN VISHNIAC—PUBLIX (TOP CENTRE) JOHN N. GERARD (OTHERS) E. S. ROSS

Cicada, *Tibicen* species, just emerged from its nymphal shell, completing a metamorphosis that lasts as long as 17 years in some species

Braconid, a parasitic wasp, laying eggs. Note long ovipositor extended from abdomen



Lacewing larva (family Chrysopidae) hatching from eggs. Each egg is borne on the end of a hairlike stalk formed of a hardened secretion

Arctiid eggs hatching on a leaf. Grown larvae are the familiar "woolly bear" caterpillars that become nocturnal moths

Newly-hatched stink bugs (family Pentatomidae) and their empty egg cases on a leaf

Aphids being born alive by parthenogenetic reproduction of wingless females. Note individual emerging from mother at right

Short-horned grasshoppers or locusts (Acrididae) mating. Eggs are laid in the soil in large masses enclosed in a capsule

Praying mantis (*Stagmomantis carolina*) with egg mass. Egg laying takes place in autumn, the eggs hatch early the following summer. Each capsule contains about 200 eggs

REPRODUCTION AND METAMORPHOSIS

PHOTOGRAPHS (TOP LEFT, BOTTOM RIGHT) JOHN H. GERARD, (OTHERS) E. S. ROSS

INSECT

Parasitic fly of central Africa with the body shape and markings of a bee, features that serve to protect it from the bees which it parasitizes

Cryptic pygmy locust (family Tetrigidae), a tiny insect that resembles the bark of a tree

Nymph of orchid mantis (*Hymenopus coronatus*). The form and coloration of the nymph serve to conceal it from its prey. The adult of this species bears little resemblance to the nymph

A mantidfly or mantispid (related to lacewings) with wings and abdomen like those of a wasp, and enlarged front legs like those of a mantis

Larva of the spicebush swallowtail butterfly (*Papilio troilus*). Large eyelike spots are merely protective coloration

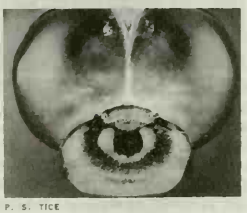
A walking stick, *Diapheroma femorata*, a phasmid, related to the mantids, coloured and shaped like a twig. These insects also assume positions that further enhance their disguise

PROTECTIVE COLORATION AND MIMICRY

PHOTOGRAPHS (TOP LEFT, TOP RIGHT, CENTRE RIGHT) E. S. ROSS, (CENTRE LEFT) J. R. HENDRICKSON FROM D. DWIGHT DAVIS, (BOTTOM RIGHT) D. DWIGHT DAVIS, (BOTTOM LEFT) JOHN H. GERARD

laying is termed the genitalia. In the female these usually serve as an ovipositor and in the Hymenoptera they are sometimes modified for sawing, boring or stinging. In the male the genitalia usually consists of clasping organs to hold the female abdomen during copulation and an intromittent organ (aedeagus) to introduce the seminal fluid.

2. Senses and Communication.—*Sight.*—The eyes are of two kinds, simple and compound. The simple eyes (ocelli) each consist of a transparent lens-shaped swelling of the cuticle and an underlying retina composed of a few dozen light-sensitive cells. In many insect larvae the ocelli occur in small groups on either side of the head and serve for the perception of objects. In adult insects the ocelli occur in addition to the compound eyes and are commonly situated in a group of three on the vertex of the head; here they seem to serve, like many other sense organs, as "stimulatory organs," which bring the insect to a state of alertness by increasing muscular tone and perhaps enhancing responses to sensory stimuli.



P. S. TICE

FIG. 3.—COMPOUND EYES OF DRAGONFLY, COMPOSED OF NUMEROUS FACETS

The compound eyes are very elaborate visual organs. They consist of large numbers of facets (some 4,000 in the housefly; 10,000 to 20,000 or more in the dragonfly), each of which has its own retinal element below. Each facet (ommatidium) receives a thin shaft of light from the object being viewed. The whole eye thus projects upon the retina a composite erect image consisting of a mosaic of points of light, each point contributed by one ommatidium. The fineness of the mosaic and thus the acuity of vision increases as the number of facets increases. It has been estimated that in the bee, under the best conditions of illumination, the resolving power of the eye (*i.e.*, the ability to perceive two closely applied lines as distinct from each other) is about one-hundredth as good as that of man.

Insects have a considerable ability to distinguish the forms of objects; bees can be trained to associate the presence of food with black figures of a particular shape on a white ground. But the chief function of the compound eyes is probably to perceive the movement of objects as the stimulating points of light pass from one ommatidium to the next.

Insects also perceive colour. The colour sense is particularly well developed in flower-visiting insects like butterflies and bees. Bees can be readily trained to come to a particular colour for food. Many insects can perceive ultra-violet light; moths, for example, will fly around a lamp that is screened by a special glass allowing passage only of ultra-violet light. (*See* VISION.)

Chemical and Mechanical Senses.—The chemical senses of taste and smell are the most remarkable of all senses in the insect. Organs of taste, which distinguish salt, sweet, sour and bitter qualities, occur chiefly around the mouth parts, and various insects (butterflies and flies) can detect sweet substances, even in very dilute solutions, in contact with the tarsi. The organs of smell are usually thin-walled hairs or minute cones situated chiefly on the antennae and palpi, often arising from the floor of a pit. The males of certain moths, which have bushy antennae covered with these organs, can smell a female a mile or more away. In bees the sense of smell seems curiously like our own, unrelated substances that smell alike to us are also confused by the bee. (*See* also SMELL AND TASTE.)

P. S. TICE

FIG. 4.—FEATHERLIKE ANTENNA OF CECROPIA MOTH

Tactile and mechanical senses are also well developed in insects. The touch receptors, consisting of hairs or bristles with movable bases, occur practically all over the body but are most abundant on the antennae. Their stimulation "informs" an insect of air currents, surface terrain and in some cases vibrations. Receptors within the body relay information as to the position of the body and its relation to the earth (senses of kinesthesis and equilibrium).

Insects can also perceive differences in temperature and humidity. The location of these senses is not always well defined, but in some insects at least they reside in the antennae. Thus the antennae, which assume such diverse forms in different insects, subserve a varied range of senses. (*See* also TOUCH, SENSE OF.)

Hearing.—Several orders of insects have evolved a special organ of hearing that consists of a diaphragm or membrane that acts much like the tympanic membrane in man. They are found in pairs, one on each side of the body, and occur chiefly in those insects that produce sound—grasshoppers, crickets, cicadas. Moths also have well-developed tympanic organs with which they apparently can hear the supersonic pulses emitted by bats, a factor that no doubt has survival value. (*See* also HEARING: *Evolution of Hearing.*)

J. M. CONRADER

FIG. 5.—AUDITORY ORGAN OF KATYDID ON UPPER END OF FORELIMB

Sound production.—The stridulations of cicadas and crickets, the humming of mosquitoes and the buzzing of bees are familiar sounds. Stridulation, usually accomplished by the male, is produced by rubbing one part of the body against another: the tips of the two forewings, the legs against the body, etc. Buzzing and humming are produced by vibrating the wings or other parts of the body. Cicadas, among the loudest insects, have resonators to amplify the sound produced by rapid vibration of a pair of membranes on the abdomen. Other noise-making insects include many beetles and termites, which make tapping sounds in wood. Although it has not been proved for all sound-making insects, sound may serve as a warning of danger and as a mating call.

3. Musculature and Locomotion.—*Walking.*—An insect walking on six legs supports itself on a tripod consisting of the anterior and posterior limb on one side and the middle limb on the other, while it carries forward the other three legs. It holds on to rough surfaces by means of claws at the extremity of its tarsi. Many insects are able to hold on to smooth surfaces by means of adhesive organs termed pulvilli. These bear numerous hairs with soft flattened extremities. It seems that when the pulvilli are drawn over a smooth surface, they become applied so closely to it that adhesion takes place and the insect is held by surface molecular forces.

The movements of insects are brought about by numerous striated muscles connecting one part of the exoskeleton with another. (In his classic work Pierre Lyonnet [1762] described 4,061 muscles in the goat moth caterpillar.) When the body wall is rigid, as in the grasshopper, the muscles run across the flexible joints from one region of firm cuticle to another. In a soft-bodied insect, such as a caterpillar or a newly molted individual, the firmness of the body wall is ensured by a general tension, or tone, in all the muscles, which sets up an even pressure upon the body fluids. Many of the movements in such an insect are brought about by the pressure of the blood acting upon points where the muscles have been relaxed.

The prodigious strength observed among insects is due in large part to the disproportionately greater amount of muscle per unit body weight. The strength of all living materials is governed by the same engineering principle that obtains in nonliving substance—as the size of any object changes (increases or decreases) its area varies as the square of linear dimensions while its volume varies

as the cube. Applied here, body weight increases as the cube of body dimensions while strength of muscle increases only as the square of muscle dimensions; it follows then that as body size decreases, the ratio of muscle strength to weight becomes progressively greater. In addition, the exoskeleton provides lightweight attachment for a marvelous fabric of tiny muscle fibres and an array of intricate pivots that afford leverage. Efficiency of insect musculature results also from the peculiar arrangement of short fibres that tend to distribute the work load evenly along certain parts of the body; *e.g.*, the chevron arrangement of muscles along the length of the femur of a grasshopper's leg.

Flight.—Some insects utilize relatively simple up and down wing movements for flight, but these movements are usually complicated by twisting and folding of the wing. The membranous area of the wing bends under air pressure while the anterior margin remains relatively rigid. As the wing moves up and down, the actual path of the wing tip is a loop or a figure eight. Among the more primitive groups, such as dragonflies and lacewings, each pair of wings moves independently. In moths and butterflies, and in bees and wasps, the wings on each side are coupled and function as one. Insects such as beetles and grasshoppers, with hardened or modified forewings, fly with the hind wings, which are usually enlarged and expanded; their flight rarely achieves the perfection, however, of moths, bees, wasps and flies.

The frequency of wing-beat varies over a wide range, from 5 per second in the butterfly *Papilio machaeon* to about 1,000 per second in the midge *Forcipomyia*. The basic movement of the wings up and down is produced by indirect muscles, which do not act on the wings themselves but distort the thoracic walls to which they are attached. These muscles have the remarkable property of being stimulated to contract whenever they are stretched. Hence two sets of muscles working in opposition can maintain a very high rate of movement, without the need for an equal number of nervous impulses per second. This indirect system governs the fundamental frequency of wing-beat, while control of flight and maneuvrability is achieved by direct muscles. These are under nervous control, and rotate the wing about a complex articulation at its base (*see* also FLIGHT [NATURAL]).

4. Feeding and Digestion.—Almost every kind of organic material can be used as food by some insect. The feeding mechanisms and the digestive processes of insects are therefore exceedingly diverse. In the more generalized forms the mouth parts (fig. 6) consist of a pair of upper and lower lips (labrum and labium), biting mandibles, and a pair of maxillae for holding and manipulating food. In more specialized insects these basic structures are modified in various ways for piercing and sucking. Cockroaches, ants, beetles and caterpillars chew their food; blood-sucking bugs and flies pierce the skin and draw out the blood; sap-sucking insects do the same thing on plants; butterflies can only imbibe fluids through the long tubelike proboscis.

The first and last segments of the gut, the fore-gut and hind-gut, are lined with thin cuticle continuous with that over the body surface. The intervening segment, the mid-gut or stomach, has the lining cells freely exposed. In insects that eat solid food the mid-gut is generally protected by a delicate detached membrane of chitin, the peritrophic membrane.

FIG. 7.—INTERNAL STRUCTURE OF FEMALE. WINGS NOT SHOWN; ORGANS SHOWN THROUGH BODY WALL

Digestive enzymes are produced in the salivary glands and in the mid-gut; they vary with the nature of the food. The absorption of the products of digestion takes place in the mid-gut, the hind-gut apparently being chiefly concerned in the absorption of water. At the dilated end of the hind-gut, the rectum, are groups of enlarged epithelial cells, the so-called "rectal glands," whose function seems to be to recover as much water as possible from the feces before they are discharged. The rectal glands may play an important part in the conservation of water in terrestrial insects.

Insects that feed on substances difficult to digest, such as wood (cellulose) or hair (keratin), commonly have digestive enzymes specially adapted to deal with them. In other insects, such as termites, great numbers of protozoans or other microorganisms, occurring naturally in the gut, serve to digest the food for their hosts.

5. Nutrition and Metabolism.—Besides fats, carbohydrates and proteins, insects require much the same range of vitamins and minerals as do mammals. They find an ample quantity of these when they feed on a mixed diet. But insects that feed solely on blood, or flour, or plant juices, generally harbour symbiotic microorganisms, often within special groups of cells called mycetomes. These microorganisms provide their hosts with the elements that are lacking in their food (*see* SYMBIOSIS).

All the chemical changes that occur in the living body are included under the term metabolism. They include the breakdown of food substances and their building up into all the complex materials needed to provide energy for movement, growth, reproduction and the elaboration of all the chemical secretions by the many glands.

Energy.—From carbohydrates, fats and proteins in the food, insects produce and store the fat and glycogen used for energy production. These are mainly stored in the so-called "fat body," in the abdomen. During starvation or hibernation the glycogen stores are first consumed and then the fat. Many insects can subsist for weeks or months upon their stores of fat.

The processes of oxidation in the body that accompany the liberation of muscular energy vary enormously in insects with the intensity of their activity. Thus on going from rest to active flight a bee may increase its oxygen consumption 48-fold. During flight a bee weighing 100 milligrams may burn sugar at the rate of 35 to 40 milligrams per hour.

Chemical Secretions.—The glands in the skin and elsewhere produce an astonishing range of chemical substances. Some of these, such as silk, wax and lac, are articles of commerce. Then there are digestive enzymes; hormones regulating development, metamorphosis and molting; complex venoms, notably in the glands of the stings in bees and wasps; formic acid in certain ant venoms; cantharidin in the beetle called "Spanish fly"; urticating substances in the hairs of caterpillars; stink glands, froth glands, scent glands and many more. (*See* HORMONES, INVERTEBRATE; INSECT BITES AND STINGS.)

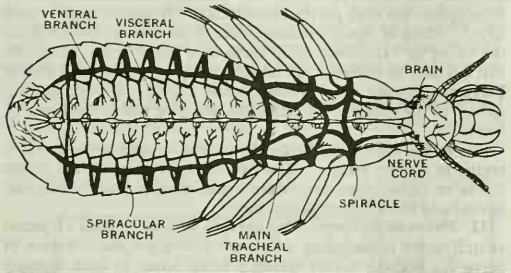
Among the most striking chemical products of insects are their pigments. Some of these, such as the yellow carotins, some anthocyanins and flavones and derivatives of chlorophyll, are derived from the plants eaten by the insects; but many of the most conspicuous pigments, such as those of pierid butterflies (pterine) appear to be by-products of metabolism. Production of such pig-

ments may be markedly affected by the surroundings; thus the chrysalids of certain butterflies adapt their coloration to that of the background on which they rest. (*See* ANIMAL COLORATION; PIGMENT, ANIMAL.)

Water Metabolism and Temperature.—The most important environmental factors that influence the physiology of insects are humidity and temperature. The retention of sufficient water in the tissues is a prime necessity of life. By having an impermeable cuticle, by keeping the spiracles closed as much as possible and by recovering water from the excreta before they are discharged, many insects, in spite of their small size, are able to exist in dry environments.

Insects are also greatly affected by temperature. They are poikilothermic (or "cold blooded") animals whose temperature is normally the same as that of their surroundings. However, if the surroundings are too cold, insects are incapable of movement. Certain butterflies at high altitudes cannot fly unless the sun is shining and their bodies are warmed by the radiant heat. During flight the contracting muscles produce enough heat to raise the body temperature far above that of the surrounding air. The large hawk moths are unable to take flight until their body temperature has been raised to 89°–97° F. (32°–36° C.) by preliminary fluttering, and during flight their temperature may rise above 105° F.

Different insects are able to resist different levels of high temperature; the largest forms can cool themselves to some extent for short periods by the evaporation of water but few can withstand temperatures much above 122° F. for a period of one hour. There are differences also in their resistance to low temperatures. Insects that pass the winter in the open in cold climates develop a condition of "cold hardiness." In this state, in which the free water content of the body is reduced, the insect can be cooled far below the true freezing point of the tissue fluids (supercooled) without the body freezing and without causing any injury. Some insects in this state can survive a temperature of −18° F. (−28° C.).



(TOP) FROM J. FOLSOM, "ENTYMOLOGY WITH SPECIAL REFERENCE TO ITS ECOLOGICAL ASPECTS"; BLAKISTON DIV., MCGRAW-HILL. (BOTTOM) A. B. KLOTS

FIG. 8.—(TOP) RESPIRATORY SYSTEM OF A GENERALIZED INSECT; (BOTTOM) MOTH CATERPILLAR WITH PROMINENT SPIRACLES

6. Respiration.—Most insects breathe by means of tracheal tubes (tracheae), which usually open at the surface of the body through a number of spiracles and which conduct oxygen to the tissues and carbon dioxide to the exterior. The tracheae are inward extensions of the cuticle in the form of tubes that branch among the internal organs. In the larger branches their walls are stiffened and prevented from collapse by a spiral thread. Their finest terminations, which are devoid of this spiral thickening, contain a variable amount of liquid and are termed tracheoles. These envelop tissues and cells and even penetrate the latter.

If the spiracles were always open, an insect would lose excessive quantities of moisture and would soon die of desiccation. Each is therefore provided with a muscular ring (or sphincter) that is held closed most of the time, being opened only at intervals as the need for exchange of gases requires. In the smaller and less active insects oxygen is conveyed from spiracles to tissues wholly by diffusion. But in larger and more active forms (grasshoppers, bees, flies, etc.) the tracheae are ventilated by alternate contraction and expansion of the body wall. These respiratory movements occur particularly during activity, and in many insects they are made more effective by the expansion of the tracheae at various points to form large thin-walled air sacs. The opening of the spiracles and the increased mechanical ventilation during activity are brought about by the accumulating carbon dioxide stimulating respiratory centres in the nervous system.

P. S. TICE

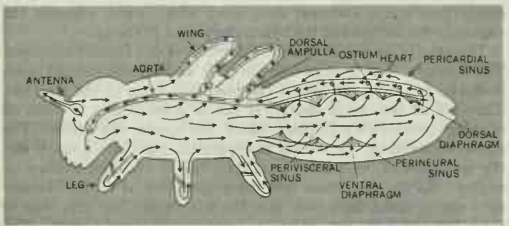
FIG. 9.—AQUATIC DOBSON FLY LARVA (HELLGRAMMITE) BEARING TUFTS OF TRACHEAL GILLS

In aquatic and in parasitic insects there are many remarkable adaptations in the respiratory system. Most of these are concerned with bringing the spiracles, often a single pair at one end of the body, into contact with the atmospheric air. But in a few larval insects the tracheal system is closed; it sends dense network of branches either to the surface layers of the body or to special outgrowths (tracheal gills), found on the body surface or, as in dragonfly larvae, within the rectum. These gills enable aquatic insects to obtain oxygen in solution in the water.

7. Blood and Associated Tissues.—Insects have an open circulation. Throughout most of the body the organs and tissues are bathed directly by the blood or hemolymph.

The fluid is kept in circulation by a dorsal vessel or heart that pumps it from the hind end of the abdomen and discharges it into the vascular space or sinus in the head (collectively, these sinuses are termed the hemocoele). The dorsal vessel is suspended by a diaphragm that separates the dorsal or pericardial sinus from the perivisceral sinus. A ventral diaphragm separates the perivisceral sinus from the ventral or perineural sinus. The blood filters back to the posterior part of the body and enters the dorsal vessel through valved openings called ostia. There are also small pumping organs or accessory hearts that ensure circulation in the wings, legs and antennae.

The blood is a clear colourless or slightly green or yellow fluid that plays little part in respiration. It contains a few white blood cells, called hemocytes, that act as phagocytes, ingesting microorganisms or debris from disintegrated cells; for the most part hemocytes do not circulate but adhere to the tissues. In a few larvae (Chironomidae or blood worms) there is hemoglobin in the



FROM H. WEBER, "GRUNDRISS DER INSEKTENKUNDE"; REPRODUCED BY PERMISSION OF GUSTAV FISCHER VERLAG

FIG. 10.—DIAGRAM OF OPEN BLOOD CIRCULATION. DIRECTION OF BLOOD FLOW INDICATED BY ARROWS

blood, and under conditions of poor oxygen supply, as when these larvae are living in mud, this pigment acts as a carrier of oxygen.

Associated with the circulatory system are other tissues that function in storage of reserves and in intermediary metabolism. Pericardial cells, which occur in little groups along the sides of the heart, remove from the blood colloidal material such as unwanted proteins derived from the breakdown of cells. The fat body is often the most conspicuous object in the insect abdomen. It serves as a store for fat, glycogen and sometimes for droplets of protein, particularly during hibernation or during the pupal stage when no food is taken. The oenocytes are large clear cells that usually occur in groups beneath the epidermis. They enlarge and become active during molting and probably secrete some of the constituents that form the cuticle.

8. Light Production.—The light-producing organs of various beetles (glowworms, fireflies, etc.) are probably derived from the fat body. They are covered by a layer of translucent cuticle. Within the cells an enzyme, luciferase, causes the oxidation of a substance, luciferin, and almost all the energy liberated appears in the form of "cold light." (*See* BIOLUMINESCENCE.)

9. Excretion.—The main excretory organs of insects are the Malpighian tubules. These are blind vessels, varying in number from 2 to 100 or more, lying freely in the body cavity and discharging into the gut at the junction of the mid-gut with the hind-gut. The urine that they produce is mixed with the residue of food from the stomach, and the mixture, after passing along the hind-gut, forms the excreta or feces. The character of the excreta depends on the type of food eaten. In the plant-sucking insects, such as aphids and leafhoppers, the feces are wholly fluid. Many insects that feed on dry foods discharge a dry powdery excrement from which every trace of water has been removed. In certain insects, notably caterpillars and the larvae of such beetles as the mealworm, which dry their excrement before discharge, the blind extremities of the Malpighian tubules are closely applied and bound to the outer wall of the rectum; the significance of this "cryptonephridial" arrangement is not fully understood.

The chief waste product in the urine is uric acid, which usually appears in solid form as granules or crystalline spheres that become more and more concentrated as the water is resorbed. In many insects uric acid, besides being discharged in the urine, accumulates in cells in other parts of the body (storage excretion). The stored granules may collect in special urate cells scattered through the fat body or in the epidermis, where they account for the chalky colouring of many caterpillars. In other insects, particularly larvae that feed inside the tissues of plants, granules of calcium carbonate may accumulate in quantity in the Malpighian tubules and as "calcospherites" in the cells of the fat body.

The excretions from the Malpighian tubules are sometimes made use of by the insect to strengthen or to colour the silken cocoon spun by the larva before pupation, and in a few insects (the ant lion larva and its allies are the best known) a part of the Malpighian tubule is actually modified to secrete silk.

10. Reproduction.—In most insects reproduction is bisexual, the egg cell produced by the female developing only after fusion with the sperm cell set free by the male. The reproductive system consists of paired sexual glands, the ovaries of the female and testes of the male, paired gonoducts into which the sexual products are discharged, and a common duct lined with cuticle, forming the vagina in the female and the ejaculatory duct in the male.

The ovaries consist of chains of developing ova termed ovarioles. The ripe egg, with a large store of yolk and a fully formed shell, is discharged from the lowest chamber or follicle of the ovariole. The shell of the egg is pierced at one or more points to form an opening (micropyle) through which the sperm can enter. The sperm received by the female at copulation pass into a small sac, the spermatheca, connected by a duct to the common oviduct or vagina. As the egg passes into the vagina several of the filamentous sperm make their way into the micropyle, but only one of these fuses with the egg nucleus and initiates its development. The sperm cells received during a single act of copulation will commonly suffice for fertilizing the eggs throughout the life of the female. In the queen bee the store of sperm received during the short nuptial flight lasts for several years.

In both sexes there are accessory glands connected with the reproductive system that may provide nourishment or a protective covering for the sex cells. In the males of some insects (Lepidoptera, many Orthoptera and Coleoptera) the sperm are not conveyed to the female in a free fluid but are enclosed in a membranous sac or spermatophore formed by the secretion of the male accessory glands. Likewise in the female, the eggs of cockroaches, locusts and some other insects are not laid singly but are cemented together in an egg capsule or oötheca.

The egg production of insects is influenced by much the same factors as is their growth. It is delayed or prevented by low temperatures or by the lack of sufficient protein. Furthermore, a hormone secreted by the corpus allatum (an endocrine gland behind the brain) is necessary. In some insects the presence of sperm in the spermatheca provides a necessary stimulus for egg production; in others a full quota of sterile eggs may be laid by the unimpregnated female. As in growth or egg development, periods of dormancy (diapause) may supervene, notably during hibernation, when no production of eggs takes place even under favourable conditions of temperature.

There are many special modes of reproduction among insects, some of them very curious. Parthenogenesis (reproduction from unfertilized eggs) occurs sporadically in many insects; in some it is constant, and males are unknown. During their summer generations aphids are both parthenogenetic and viviparous (bear young alive). Birth of newly hatched larvae is common in certain flies; the tsetse fly (*Glossina*) gives birth to a single full-grown larva that has been nourished in the uterine cavity by special milk glands. Polyembryony occurs in various parasitic insects; a single egg will spit up in the course of development and give rise to hundreds of larvae.

One of the most remarkable phenomena is paedogenesis, which occurs in certain midges. The ova in the young ovaries of the larvae or pupae ripen prematurely and develop into larvae that devour and disrupt their parent host.

11. Nervous System.—The nervous system consists of paired ventral nerve cords, along which are strung ganglia (clusters of nerve cell bodies), a pair typically being found in each segment of the thorax and abdomen. The nerve cords, which are closely applied during most of their course, separate in the head to loop around the digestive tract, forming the circumesophageal commissure. This commissure unites the supraesophageal ganglion (or brain), which receives the nerves from the great sense organs on the head and co-ordinates behaviour, and the subesophageal ganglion, which innervates the feeding parts. The series of segmental ganglia throughout the thorax and abdomen supply nerves to muscles and sense organs of their own segments.

FROM R. SNODGRASS, "PRINCIPLES OF INSECT MORPHOLOGY", REPRODUCED BY PERMISSION OF MCGRAW HILL BOOK CO.

FIG. 11.—NERVOUS SYSTEM, DISSECTION OF A GRASSHOPPER

To an extent that varies in the different groups of insects, the ganglia become partially fused with one another. None of the ganglia contains centres absolutely vital to the insect: an insect deprived of the brain and subesophageal ganglion can still live and walk; the isolated abdomen can still lay eggs. The individual ganglia can in fact serve as the centres for the simpler reflex actions, such as the withdrawal of the leg on pressure. They can even effect the degree of co-ordination necessary for walking. But for the co-ordination of all the complex reactions the brain is necessary. (*See* also NEUROLOGY, COMPARATIVE.)

12. Behaviour.—Some insect behaviour consists in fixed responses to stimuli such as light, temperature, water, chemicals, gravity, air currents, etc. Since reception of and response to stimuli are mediated by the nervous system, which is genetically determined, behaviour in such cases is largely automatic. Other kinds of insects can learn by experience, the best known instances being found among the ants, bees and wasps. The study of insect behaviour is still in its infancy and offers a promising field for investigation. (*See* ANIMAL BEHAVIOUR; SOCIOLOGY, ANIMAL; PSYCHOLOGY, COMPARATIVE; SOCIAL INSECTS.)

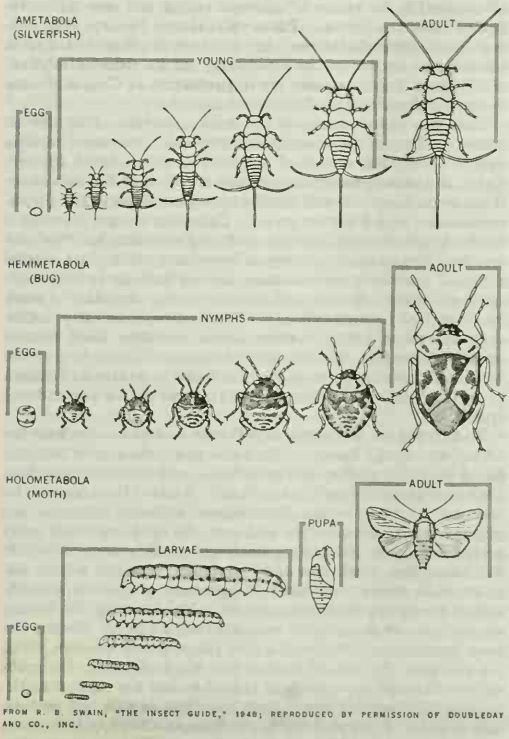
Migratory behaviour, well known among the locusts (certain grasshoppers of the family Acrididae) and some butterflies, is found in many other winged insects as well. (*See* MIGRATION, ANIMAL.)

III. LIFE HISTORY

1. Development.—Most insects start to develop within an egg that is covered by a hard shell, the chorion. Some eggs are completely watertight and can withstand exposure in the open for months without drying. Eggs laid in the earth or inserted into plant stems, etc., are able to absorb moisture from their surroundings. Many insects pass the winter in the egg stage. In these, embryonic development is arrested and the organism goes into a state of dormancy or diapause, until conditions are more favourable.

When the young insect is fully developed, it may chew its way out of the egg, if it has biting mouth parts, or force off an egg cap or cut an opening in the shell by means of "hatching spines" of varying types. The young insect aids itself in this process by swallowing air, and when it is free from the shell, it distends itself with still more air so that the newly hatched insect is always much larger than the egg from which it has come.

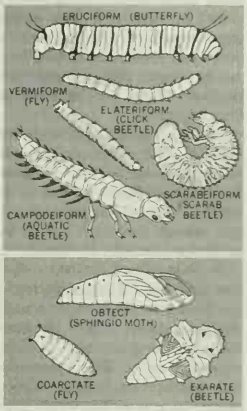
2. Growth and Moulting.—The newly hatched insect is covered by a cuticle that is flexible enough to allow movement of the parts but rigid enough to serve as a skeleton to which the muscles are attached. The rigid parts are incapable of stretching or of growth. To permit growth, the old cuticle is shed from time to time, a new and larger cuticle first having been formed beneath, folded and compressed, and thereby exerting a pressure that helps to force off the old cuticle. This process is initiated by a hormone and is termed moulting or ecdysis, the periods between successive moults being called stadia and the insect forms being called instars. The epidermis separates from the old skin and the cells divide and arrange themselves in proper form and then lay down the new cuticle. Meanwhile the old endocuticle is digested and the products are absorbed through the new cuticle. In the young stages of insects there are always certain lines of weakness, usually in the middle of the thorax, where the exocuticle is lacking. When the new cuticle is formed and digestion of the old is complete, the old skin splits along these lines and the insect can escape from its old skin. At this critical stage, when the new cuticle is colourless and soft, the insect is most vulnerable. It proceeds immediately to swallow air and distend itself to its full size. It contracts its muscles and so forces the body fluid into the wings, when present, causing them to expand. It then sets in motion the oxidative processes within the cuticle that lead to the hardening and darkening of the skin.



FROM R. B. SWAIN, "THE INSECT GUIDE," 1948; REPRODUCED BY PERMISSION OF DOUBLEDAY AND CO., INC.

FIG. 12.—TYPES OF DEVELOPMENT

3. Metamorphosis.—As growth proceeds through successive molts, the more primitive, wingless insects change little, each succeeding instar merely increasing in size. However, most insects pass through striking changes of form, or metamorphosis, at the last molt, when the adult stage is reached, and in certain groups the final stage is preceded by an inactive pupa. Metamorphosis, like the molting process that permits it, is controlled by hormones. The various types of metamorphosis (or lack of it) exhibited by insects after leaving the egg express fundamental evolutionary relationships. These are commonly classified as follows:



SECOND FROM TOP FROM E. L. PALMER, "FIELD-BOOK OF NATURAL HISTORY", REPRODUCED BY PERMISSION OF MCGRAW HILL BOOK CO.; ALL OTHERS FROM KLOTS AND KLOTS, "1001 QUESTIONS ANSWERED ABOUT INSECTS," DODD, MEAD AND CO.

FIG. 13.—TYPES OF LARVAE AND PUPAE

Ametabola.—Insects that develop directly without change in form from newly hatched nymph to adult, the adults being primitively wingless. Examples are springtails, silverfish, etc.

Prometabola.—Insects that pass through two distinct immature stages, an aquatic nymph and a winged young adult (subimago), before transforming to a sexually mature adult (imago). Only the May flies have this type of development.

Hemimetabola.—Insects in which metamorphosis occurs between the last nymphal stage and the imago. There is no subimago and no pupal stage. Examples are the dragonflies, stone flies, cockroaches, grasshoppers, lice, aphids, etc. (Secondarily wingless groups in this series are assigned here on other grounds, since their metamorphosis is less pronounced than in winged forms.)

Holometabola.—Insects that develop through a resting stage (prepupa and pupa) between the larva (rather than nymph) and the adult. The wings develop internally in the last larval stage (prepupa) and evert from sacs to an external position on the pupa. The larvae have no external wing pads and may be campodeiform (*i.e.*, like the larvae of *Campodea*, a genus of diplurans or twintails), eruciform (caterpillarlike), scarabaeiform (grublike), elateriform (wirewormlike) or vermiform (maggotlike). Three principal types of pupae occur: obtect, with the appendages stuck to the body; exarate, with the appendages free from the body; and coarctate, like exarate, but having a hard, smooth covering (puparium). Examples are lacewings, butterflies and moths, true flies,

fleas, beetles, ants, bees and wasps, etc.

Hypermetamorphosis, in which the different larval instars vary in form, often changing from an active campodeiform stage to more sedentary vermiform or scarabaeiform larva, occurs in some beetles and neuropterans, in twisted-wing insects and in a few true flies and hymenopterans.

IV. IMPORTANCE OF INSECTS

A. Beneficial Insects

Most of the species of insects now known are beneficial or useful to man and are important in the balance of nature.

1. Pollination.—The evolution of some insects is closely associated with the evolution of flowers, a relationship of interdependence that exists today notably among the hymenopterans and a few other groups. As a result, most of the higher plants are insect pollinated, although a number have their pollen carried by other agencies, including bats, birds and wind. Insect-pollinated plants include most fruit and seed crops, which depend entirely upon insects or require them for maximum production. A great variety of insects contribute to pollination, but the most important are bees and wasps, butterflies and moths, flies and gnats and beetles. Moths are the major pollinators of the nighttime, bees of the daytime.

In some cases, rather complex methods are used to achieve pollination. For example, the yucca moth, sole pollinator of the yucca Spanish bayonet, inserts her eggs into the ovary of the flower, then forces a wad of pollen into the long funnel-shaped stigma. The developing larvae eat some of the developing seeds but enough seeds are left to insure survival of the yucca—a remarkable example of interdependence of an insect and a plant.

2. Balance of Nature.—*Regulation of Density Among Plants and Animals.*—The populations of plants and animals that make up the living world exist in a natural balance that is regulated and maintained very largely by parasitic and predaceous organisms. In this system, plant- and animal-feeding insects play an extremely important role. This becomes clear immediately when man alters this balance by various agricultural practices. Garden plants moved to new regions where their natural enemies do not occur may become serious weeds, as happened when opuntia cactus was introduced to Australia, lantana to Hawaii, and St.-John's-wort to California. Likewise, insects carried about the world by commerce, without their natural enemies, have become serious pests, and the restoration of the natural balance in such cases is a principal objective of biological control (*see* Entomology).

Improvement of Soil and Disposal of Waste.—The large numbers of insects that live in the soil, including some that are injurious to the roots of plants, improve the quality of the soil by bringing earth to the surface from deeper layers, contributing to the humus and increasing air penetration. Others, by their scavenging, hasten the decay of dead organisms and thus contribute to the cycle that involves all life and improves the environment of man.

Provision of Food for Other Useful Animals.—Insects provide the principal food for trout and other fresh-water game fish, for many game birds and songbirds and for some of the fur-bearing and game animals of tropical regions.

3. Useful Products.—Throughout recorded history man has made use of insect products. Some of these, like the silk of commerce, shellac and beeswax are body secretions of insects. Others, as cochineal and crimson-lake dyes and medicinal substances such as cantharidin and bee venom, are extracts. Whole insects and their larvae have long been familiar food in certain parts of the world and are exotic specialty or gourmet items in some western countries. However, the food most consistently derived from insects has been honey, collected from flowers in the form of nectar and elaborated and concentrated by the honeybee.

4. Scientific and Aesthetic Value.—Their small size, great diversity and special adaptations have made insects popular subjects of study. They have yielded some of the most convincing data in support of the theory of evolution. These include protective coloration and mimicry, polymorphism, geographical variation, host specificity and other phenomena. The vinegar or pomace fly (*Drosophila*), because of its ease of handling, its reproductive capacity and short life cycle and its giant chromosomes of the salivary gland, has been a major tool of the geneticist; other insects also are yielding data fundamental to an understanding of animal physiology and animal ecology. (*See* Entomology.)

Finally, insects yield much of aesthetic value to mankind. They have been used directly in ornaments and jewelry, and their shapes and patterns have been widely copied in the decorative arts. They have inspired numerous songs, poems and stories and have provided enjoyment for thousands of amateur collectors and hobbyists. Their own songs and chirps and the colour and flash of their wings add much to the enjoyment of human life.

B. Harmful Insects

Although by far the majority of insects benefit man directly or indirectly, the best known species are those that he considers injurious. These fall into two major categories—those that attack and annoy man and other living animals, and those that attack man's crops and plant products. The control of these pests constitutes the major objective of the applied fields of medical and veterinary entomology and of agricultural and forest entomology, respectively.

1. Effects on Man's Health.—Insects that annoy man include flies, mosquitoes, ants, bees and wasps, which are encountered largely in the out-of-doors but which frequently may invade his dwelling places (*see* Insect Bites and Stings). Others, such as lice and fleas, are more intimately associated with man, living on his body as parasites. By far the most important, however, are the insects that carry other parasites on or in their bodies or that serve as hosts for causal organisms of certain human diseases that could not exist without the insect.

Among the more important diseases carried by insects, the following may be mentioned. The cockroach (*q.v.*) can carry agents of typhoid, cholera and possibly leprosy (*qq.v.*). The body louse (*Pediculus*) is the vector of epidemic typhus and also carries relapsing fever (*see* Typhus Fever; Relapsing Fever). The bedbug (*q.v.; Cimex lectularius*) has not been implicated in disease transmission outside of the laboratory, but its reduviid relatives of the genus *Triatoma* carry the trypanosomes of Chagas' disease in tropical America (*see* Trypanosomiasis).

True flies include some of the most important of all disease vectors. Among the mosquitoes, *Anopheles* transmits malaria (*q.v.*); *Aedes*, the viruses of dengue and yellow fever (*qq.v.*); *Culex*, and other genera, the causative organism of filariasis (*q.v.; Wuchereria bancrofti*) and various viral illnesses including the encephalitides (*see* Encephalitis). *Culicoides* midges transmit a relatively unimportant filariasis-producing organism, but *Phlebotomus* sand flies transmit *Leishmania* organisms, which cause oriental sore and espundia; trypanosomes causing kala azar; *Bartonella* causing Carrión's disease; and viruses causing pappataci or sandfly fever (*see* Leishmaniasis). Finally, *Simuliam* carry onchocerciasis; tabanid flies, various worms including those causing loaiasis; tsetse flies, trypanosomes of sleeping sickness (*q.v.*); and house flies, which may spread typhoid fever, dysentery and cholera (*see* Housefly). Fleas are able to transmit plague and endemic typhus.

2. Attacks on Domestic and Game Animals.—Sucking lice (Anoplura) attack horses, cattle, swine and various game animals; biting lice infest poultry and game birds; and fleas feed upon both birds and mammals (*see* Louse; Flea). Some of these insects also transmit avian and mammalian diseases, including tularemia and plague (*qq.v.*). However, as with man, the most important insect pests of domestic and game animals are the flies, some of which, like tsetse flies, black flies and mosquitoes, transmit serious diseases, while others cause localized irritations of the eyes, nostrils, ears or alimentary canal, or cause loss of blood through the feeding of adults or of parasitic or wound-infesting larvae. Among the most important are the warble flies (*Hypoderma* species), which are prevalent throughout Europe and North America; the grubs migrate through the body and lodge beneath the skin of cattle, causing irritation and loss of flesh, reduction of milk and perforation of hides. In Central and South America *Dermatobia hominis*, sometimes called the human botfly because it attacks man, also

infests cattle and other domestic animals. Horse botflies (*Gasterophilus* species) attach their eggs to the hairs of the animal; when swallowed, the eggs hatch into larvae that develop in the stomach and intestine of the host. The larvae of the sheep botfly (*Oestrus ovis*) infest the sinuses of the heads of sheep, and the sheep ked (*Melophagus ovinus*), a ticklike blood-sucking fly, is especially harmful to lambs; both are species of world-wide distribution. (*See* BOTFLY.) The sheep blowflies (Calliphoridae) infest the wool and skin of the animals, causing septic wounds that may result in the death of the hosts; serious losses from these insects are suffered in Australia (*see* BLOWFLY). Another fly, *Wohlfahrtia magnifica*, similarly infests sheep in the U.S.S.R. Screwworms, larvae of flies of the genus *Callitroga*, infest the decaying flesh of the wounds of cattle and goats, sometimes invading the living tissues and producing lesions that often lead to death (*see* SCREWWORM). The horn flies, or buffalo flies (*Siphona* species), are responsible for severe losses to cattle, notably in the United States and Australia. Other biting flies that annoy animals include the stable fly (*Stomoxys calcitrans*), black flies (Simuliidae) and horse flies (Tabanidae) (*see* BLACK FLY; HORSE FLY). (*See* also FLY; BACTERIAL AND INFECTIOUS DISEASES; PARASITOLOGY.)

3. Injury to Plants.—*Cultivated Crops.*—Practically all of the crops grown by man have important insect pests. The stems and shoots of cereals are infested by the frit fly (*q.v.; Oscinella frit*) and gout fly (*Chlorops pumilionis*) in Europe, and the Hessian fly (*q.v.; Mayetiola destructor*), in Europe but more destructive as introduced in North America. The European corn borer (*q.v.; Pyrausta nubilalis*) has also become a serious pest of corn (maize) in North America. Several noctuid moths of the genera *Busseola* and *Sesamia*, and pyralid moths, especially *Chilo*, have larvae that are stem borers of maize and of sorghum, millet and rice in different parts of Africa and Asia. The chinch bug (*q.v.; Blissus leucopterus*) seriously affects all cereal crops in the central United States, and the grain pest (*Eurygaster integriceps*) sucks the young grains of cereals in the middle east and southern U.S.S.R. Wireworms (*q.v.;* larvae of elaterid beetles) are widespread root-feeding pests of cereals. Outbreaks of army worms (*q.v.*) and cutworms (larvae of noctuid moths) destroy crops of all kinds, including pasture plants, as do locusts and grasshoppers (*qq.v.*). Clovers and alfalfa (lucerne) are injured by leaf-feeding caterpillars (*Colias*) and root-feeding larvae of weevils (*Sitona*); in the western United States the spotted alfalfa aphid (*Therioaphis maculata*) is a very important pest (*see* WEEVIL; APHID). Vegetable pests in both Europe and North America include the onion maggot (*Hylemyia antiqua*), cabbage maggot (*H. brassicae*) and the carrot rust fly (*Psila rosae*). The cabbage butterfly (*Pieris rapae*), a migratory species of European origin, has spread to North America and also to New Zealand and Australia. The Colorado potato beetle (*q.v.; Leptinotarsa decemlineata*), originally associated with wild *Solanum* in the Rocky Mountains, has spread eastward in North America and has also become established in western Europe. Also in Europe, beans, mangels and sugar beets are infested by the bean aphid (*Aphis fabae*), while flea beetles (*Phyllotreta* species) riddle the foliage and destroy the seedlings of cruciferous crops. The most serious enemy of beans in North America is the Mexican bean beetle (*Epilachna varivestis*), which has spread from the western states.

In many parts of the world the developing flower buds and bolls of cotton are attacked by the pink bollworm (*Pectinophora gossypiella*) and by larvae of several genera of Noctuidae, one of which (*Heliothis*) similarly affects maize, tobacco and many vegetable and pulse crops. The boll weevil (*q.v.; Anthonomus grandis*) is the most important native pest of cotton in North America. Plant injury is caused by the cotton fleahopper (*Psallus seriatus*) and related mirid bugs (*Lygus*) in the United States; cotton foliage is eaten by larvae of the migratory moth *Alabama argillacea* in many parts of the new world and "scorched" by the feeding of cicadellids (*Empoasca* species) in the old.

Sugar cane is attacked by moth borers, notably *Diatraea saccharalis* and related species in the western hemisphere and other genera of the Pyralidae in the old world. Other important sugar-cane pests include white grubs (larvae of scarab beetles), a froghopper (*Aeneolamia varia*) in Trinidad and a leafhopper (*Perkinsiella saccharicida*) that has become established in many sugar-growing countries. Tobacco is injured in the new world by tobacco flea beetles (*Epitrix* species), the budworm (*Heliothis virescens*) and several species of hornworms (Sphingidae), while cutworms are troublesome everywhere. Tea has many pests, of which the shot-hole beetle (*Xyleborus fornicatus*) in Ceylon and the tea mosquito bug (*Helopeltis*) in Asia and Africa are important examples. The young shoots of cacao are attacked in West Africa by cacao mirids (*Sahlbergella* and *Distantiella*), causing "dieback." The numerous pests of coffee include moth and beetle larvae that bore in the wood and leaf miners and scale insects that damage leaves and stems. The coffee berry borer (*Stephanoderes hampei*) is particularly destructive in Africa, Java and Brazil, while in eastern Africa a pentatomid bug (*Antestiopsis*) causes serious damage to *arabica* coffee. Among tropical crops, coconut palms are attacked by rhinoceros beetles, one of which (*Oryctes rhinoceros*) is spreading among the Pacific islands, and by species of coreid bugs that cause premature falling of the nuts. Bananas are attacked by the widespread banana weevil (*Cosmopolites sordidus*) and sweet potatoes by the sweet potato weevil (*Cylas formicarius*). The sisal weevil (*Scyphophorus interstitialis*), a new-world species, has become established in eastern Africa.

Some of the important insect enemies of fruit and fruit trees are very widely distributed, such as the codling moth (*q.v.; Carpocapsa pomonella*) on apple, stone fruits and walnuts; the oriental fruit moth (*Laspeyresia molesta*) on stone fruit; the woolly aphid (*Eriosoma lanigerum*) on apple; and the San José scale (*Aspidiotus perniciosus*) on most deciduous fruit trees and bushes (*see* SCALE INSECT). European insect pests include the apple blossom weevil (*Anthonomus pomorum*) and several species of sawfly (*q.v.; Hoplocampa*) on top fruit. The European currant clearwing moth (*Aegeria tipuliformis*) has spread to other temperate regions; a related species, the peach-tree borer (*A. exitiosa*) is confined to North America, as are two other important pests, the plum curculio (*Conotrachelus nenuphar*) and the apple maggot (*Rhagoletis pomonella*). The root-attacking grape phylloxera (*Phylloxera vitifoliae*), of American origin, once destroyed thousands of acres of vineyard in Europe and California but is now controlled by the use of resistant root-stocks (*see* PHYLLOXERA); the fruits are attacked in America by the larvae of the grape berry moth (*Paralobesia viteana*) and in Europe by the related *Lobesia botrana*. Citrus insects are legion, some species being distributed over the entire tropical and subtropical world. Most important are the scale insects and mealy bugs (Coccidae), including the black scale (*Saissetia oleae*), Florida red scale (*Chrysomphalus ficus*), California red scale (*Aonidiella aurantii*) and purple scale (*Lepidosaphes beckii*). The citrus white fly (*Dialeurodes citri*) and the citrus black fly (*Aleurocanthus woglumi*) are important pests not only of citrus fruits but also of many other plants. The Mediterranean fruit fly (*Ceratitis capitata*) is perhaps the greatest of all fruit pests, affecting deciduous fruits as well as citrus; it has twice been eradicated from Florida. Other important fruit flies (Trypetidae) are the Mexican fruit fly (*Anastrepha ludens*), which annually invades southern Texas; the oriental fruit fly (*Dacus dorsalis*), now established in Hawaii, and related species in Australia; and the olive fly (*Dacus oleae*), a major pest in the Mediterranean region.

Transmission of Plant Diseases.—Just as insects transmit diseases of man and animals, they also play an important role in the dissemination of the bacteria, fungi and viruses that cause plant diseases. Transmission may involve simply the transport of the disease agent on the body appendages; more complex relationships occur where the disease organism passes through or multiplies within the insect tissues. The bacterium *Erwinia amylovora*, which causes fire blight, a serious disease of pears, apples and other orchard fruits in North America, is associated with many species and several orders of insects. Several related bacteria cause diseases in other plants and are believed to be insect-transmitted. The fungus *Ceratostomella ulmi*, responsible for Dutch elm disease (*see* ELM) in Europe and (since 1930) North America, and other species of *Ceratostomella* that cause blue stain

of coniferous timbers, are transmitted mechanically by bark beetles (Scolytidae). Cotton throughout the tropics is seriously affected by yeastlike fungi (*Nematospora* species) that cause internal boll disease and are transmitted via the mouth parts of stainer bugs, notably *Dysdercus* species; pentatomid bugs (*Antestiopsis* species) transmit a related fungus that seriously affects coffee berries in East Africa.

Many important plant diseases are caused by viruses, the majority of which are insect-transmitted, mainly by sucking bugs, though in a few cases chewing insects such as beetles or grasshoppers have been implicated. Transmission by the latter is purely mechanical, resulting from contamination of the mouth parts. The viruses that cause sugar-cane mosaic and potato mosaic (Y-type) can be transmitted by several kinds of aphids for a short time after these have fed, their effectiveness being increased by previous fasting. The transmission of such nonpersistent viruses seems essentially mechanical, though affected by compatibility of the virus, the aphid saliva and plant tissues inoculated. The persistent viruses, on the other hand, are characterized by a latent period following acquisition by the vector. This may last several weeks, during which the virus is not transmitted, but afterward transmissibility is extended, often throughout the vector's life. The latent period is occupied by the passage of the virus through the insect, from the intestine to the salivary glands; in some cases the virus multiplies within the vector, and in at least one (stunt disease of rice in the far east, carried by the rice leafhopper, *Nephotettix apicalis*) it is passed on to the next generation of the vector via the egg. Persistent viruses tend to be highly specific and many are transmitted by leafhoppers, including curly top of sugar beet (spread by *Circulifer tenellus*) and aster yellows (transmitted to many crop plants by *Macrosteles fascifrons*) in North America; maize streak in southern Africa (by *Cicadulina mbila*); and yellow dwarf of tobacco in Australia (by *Orosius argentatus*). The cosmopolitan green peach aphid (*Myzus persicae*) transmits potato leaf roll in North America and Europe, sugar-beet yellows in Europe and a score of other virus diseases; and *Aphis craccivora* spreads rosette disease of peanuts in Africa. Leaf curl of cotton in the Sudan is carried by the white fly *Bemisia tabaci*, and swollen-shoot disease of cacao in West Africa by the mealy bug *Pseudococcus njalensis*. (*See* PLANT DISEASES.)

Forest and Shade Trees and Timbers.—Forest trees are defoliated by numerous caterpillars; in Europe notably those of the nun moth (*Lymantria monacha*) on spruce, winter moth (*Operophtera brumata*) and mottled umber moth (*Erannis defoliaria*) on broad-leaved trees and pine looper (*Bupalus piniarius*) and pine shoot moth (*Evetria buoliana*); in North America those of the gypsy moth (*Lymantria dispar*), brown-tail moth (*Euproctis chrysorrhoea*), spruce budworm (*Choristoneura fumiferana*), larch case-bearer (*Coleophora laricella*) and various tent caterpillars (*Malacosoma* species). The gypsy and brown-tail moths were introduced into Massachusetts from Europe and have spread over New England in spite of vigorous efforts to eradicate them. The North American fall webworm (*Hyphantria cunea*) was accidentally introduced into central Europe, where it has become a pest of shade trees. The Japanese beetle (*Popillia japonica*), of only local importance in Japan, has infested a large area in the United States, defoliating shade and fruit trees. Weevils (*Hylobius abietis* and *Pissodes pini*) attack the growing shoots of pines. Bark beetles (*Ips* and *Dendroctonus* species) are responsible for much damage to northern forests, especially in North America. Other wood-boring beetles, especially Cerambycidae, attack a great variety of park and woodland trees. Indian forests suffer extensive damage from the sal borer (*Hoplocerambyx spinicornis*), while the eastern African long-horned beetle (*Oemida gahani*) is a dead-wood feeder that particularly attacks *Podocarpus* timber. In many parts of the world, the old house borer (*Hylotrupes bajulus*) seriously infests seasoned softwood roof timbers. Wood wasps (Siricidae) and wood-boring caterpillars (Cossidae) are injurious in many parts of the world, but the particular enemies of structural timbers and furniture are anobiid and lyctid beetles, notably the furniture beetle (*Anobium punctatum*), the notorious deathwatch beetle (*Xestobium rufovillosum*) and the powder-post beetles (*Lyctus* species). The majority of termites are earth-dwelling species that attack any wood in contact with the ground or accessible via the earth-covered runways they build across the surface of intervening materials; the dry-wood termites, which are independent of the ground, include several dangerous and widely transported species (*see* TERMITE).

4. Damage to Stored and Manufactured Goods.—Many insects, mostly beetles and moths, subsist on stored or manufactured products of vegetable or animal origin. Most have been widely distributed through commerce. The granary and rice weevils (*Calandra granaria* and *C. oryzae*), lesser grain borer (*Rhizopertha dominica*) and Angoumois grain moth (*Sitotroga cerealella*) prefer whole grains; the saw-toothed grain beetle (*Oryzaephilus surinamensis*), flour beetles (*Tribolium* species), mealworms (*Tenebrio* species), Mediterranean flour moth (*Ephestia kuehniella*) and Indian meal moth (*Plodia interpunctella*) prefer flour or coarsely ground cereals. Beans are attacked by bruchid beetles, peanuts and grains by the khapra beetle (*Trogoderma granaria*) and nuts and dried fruits by the almond moth (*Ephestia cautella*) and cacao moth (*E. elutella*). The drugstore beetle (*Stegobium paniceum*) and the cigarette beetle (*Lasioderma sericorne*) infest tobacco, drugs and spices, while the larder beetle (*Dermestes lardarius*) and cheese skipper (*Piophila casei*) are important pests of bacon, cheese and similar products. Woolen clothing, rugs, hair and feathers are damaged by clothes moth larvae (*Tineola bisselliella* and *Tinea pellionella*) and by carpet beetles (Dermestidae).

V. ORIGIN AND EVOLUTION OF INSECTS

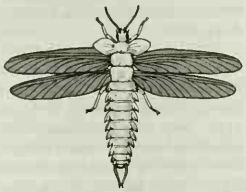
The fossil record indicates that insects existed at least 250,000,000 years before man; that they learned to fly at least 50,000,000 years before reptiles and birds; that some groups of insects have evolved rapidly and become extinct while others have persisted with relatively little change from the Carboniferous period into modern times. However, there are extensive gaps in the fossil record. Most insects are of small size, with delicate structures, and their skeletal parts are not preserved as readily as those of many other groups of animals. Special materials such as shale-forming volcanic ash and mud, concretions, coal-forming plant humus and amber-forming plant resins, have yielded the best fossil insects. Although the fossil record is the major direct source of data on the origin of insects and their early evolution, much can be inferred from the comparative morphology, zoogeography and comparative ecology of living forms.

1. Insect Ancestors.—If the facts of insect origin are preserved in the fossil record, they, no doubt, remain to be discovered among the rocks of the Palaeozoic era. It is known that many groups of invertebrates existed in the early Palaeozoic that might have given rise to the insect line. Included were other arthropods, such as trilobites, eurypterids, scorpions, crustaceans, millipedes and centipedes, and polychaete worms. Each of these has been regarded as ancestral to, or sharing common ancestry with, insects. Modern opinion seems to favour common ancestry with a group of arthropods that were already adapted to air-breathing and that resembled modern millipedes.

2. The First Insects.—Most students of insect evolution agree that the first insects were wingless, terrestrial forms, represented among living groups by the orders Thysanura (bristletails) and Diplura (twintails). This conclusion, however, is based upon a study of modern types, since these creatures are extremely fragile, with little chance of fossil preservation. Although the earliest records of insects accepted by most authorities extend back only so far as the Triassic period, it is generally postulated that they must have existed in the Devonian period, perhaps 325,000,000 years ago.

3. Evolution of Wings.—The first major departure in the evolution of insects, if the above views are correct, was the development of wings. Again, the fossil record does not date this event precisely but it must have occurred in the Lower Carboniferous period, perhaps 275,000,000 years ago, since the fossil winged forms of the earliest of the Upper Carboniferous strata are diverse, representing several orders. The evolutionary process that provided the insect wing is not clearly understood, but fossil evidence sug-

gests that wings were derived from the second and third pairs of a set of membranous expansions (paranota) on the dorsum of each of the three thoracic segments. These paranota were present on many kinds of early winged insects, and contained veins and minute hairs like those characteristic of wings. In any event, the first winged insects had a simple articulation and were unable to fold the wings back over the body. These creatures, the Palaeoptera, some of which had wing spans of 30 in., are represented today by the Odonata (dragonflies) and Ephemeroptera (May flies). Wing-flexing insects (Neoptera) do not appear in the fossil record until somewhat later, suggesting that they may have been derived from the Palaeoptera. However, some students support the view that wings arose more than once among the insects.



FROM A. D. IMMS, "INSECT NATURAL HISTORY," WILLIAM COLLINS & CO. LTD., LONDON

FIG. 14.—RESTORATION OF A FOSSIL INSECT SHOWING WINGLIKE EXPANSIONS (PARANOTA) ON THE PROTHORAX AND TWO PAIRS OF WINGS

Wings offered great advantages to the insects by providing a ready means of avoiding terrestrial predators and greatly increased their means for dispersal. The wing-flexing neopteran types were the more successful. They could protect their wings when not in flight, reduce their conspicuousness, and gain access to cracks and crevices in which to seek further protection. Also, a more complicated articulation allows much greater control of the wing during flight. Most orders of living insects are of the neopteran line.

Concurrent with the evolution of the insect wing was the requirement that the developing insect pass through distinct growth phases or metamorphosis. The early neopterous insects developed through a series of nymphal stages and gradually approached the adult form, exhibiting incomplete metamorphosis. Presumably the nymphs had food habits similar to the adults and resembled them in most aspects except that they lacked the ability to fly. Modern representatives of this line (Hemimetabola) include such groups as the Orthoptera (grasshoppers, crickets, katydids), Hemiptera (true bugs, cicadas, aphids, etc.) and various smaller orders of biting and sucking insects.

4. Evolution of Complete Metamorphosis.—The second major step in the evolution of the insects came with the advent of complete metamorphosis, a type of development in which the larval stages (grubs, maggots, caterpillars) are very different from the adult and capable of living in quite different ecological niches. The transformation to the adult is made during a transitional stage (pupa), which often has the additional advantage of carrying the insect through unfavourable periods for adult or larval activity. Since complete metamorphosis appears to have been evolved during the climatic extremes of the Permian period, it may have principally served this function originally. The ability of insect larvae to live in a different environment from the adult and to utilize different kinds of food permitted them to invade plant and animal tissue, as internal parasites, while the adult remained free-living. The great versatility inherent in this system and the large number of new environments made available for exploitation proved extremely advantageous to the holometabolous groups. Although the Holometabola do not appear in the fossil record until the Lower Permian period, nearly 90% of living species have this type of metamorphosis, including the members of the largest orders, the Coleoptera (beetles, weevils), Hymenoptera (ants, bees, wasps), Lepidoptera (butterflies, moths) and Diptera (true flies).

See also ANIMALS, PHYLOGENY OF; METAMORPHOSIS.

VI. CLASSIFICATION

The classification of insects, like that of other animals, is divided into a hierarchy of categories designed to represent various degrees of relationship. In view of the size and diversity of the class Insecta, it is not surprising to find many differences of opinion among entomologists as to the arrangement and limits of the subgroups. Subclass names are here based on the primitive presence or absence of wings. Forms that are primitively wingless are placed in the Apterygota; winged insects, even though secondarily wingless, are of the Pterygota. In some classifications the type of metamorphosis is used for the subclass name. The following classification, recognizing 31 orders, may differ in some respects with the arrangements given in related articles elsewhere in the encyclopaedia; these differences reflect the viewpoints of the various authors concerned.

Subclass Apterygota
(Ametabola)
Order Collembola, springtails
" Protura, proturans or telsontails
" Diplura, diplurans or twintails
" Thysanura, bristletails, silverfish, firebrats
Subclass Pterygota
(Prometabola)
Order Ephemeroptera, May flies
(Hemimetabola)
Order Odonata, dragonflies, damsel flies
" Blattaria, cockroaches
" Mantodea, mantids
" Phasmida, stick and leaf insects
" Isoptera, termites
" Dermaptera, earwigs
" Orthoptera, grasshoppers, crickets, katydids, etc.
" Embioptera, embiids or web-spinners
" Plecoptera, stone flies
" Zoraptera, zoraperans
" Corrodentia (Psocoptera), book lice, bark lice
" Mallophaga, biting lice, bird lice
" Anoplura, sucking lice
" Thysanoptera, thrips
" Hemiptera, true bugs and allies
(Holometabola)
Order Coleoptera, beetles, weevils
" Strepsiptera, stylopids or twisted-wing insects
" Megaloptera, dobson flies, alder flies, etc.
" Neuroptera, ant lions, lacewings, mantispids, etc.
" Raphidioidea, snake flies
" Mecoptera, scorpion flies
" Trichoptera, caddis flies
" Lepidoptera, butterflies, moths
" Diptera, true flies
" Siphonaptera, fleas
" Hymenoptera, ants, bees, wasps, etc.

The relationships and taxonomic rank within the Apterygota are still uncertainly known and therefore matters of dispute among authorities (*see* APTERYGOTA; ARTHROPODA). Cockroaches and mantids are considered by some as being suborders (Blattodea and Mantodea, respectively) of the order Dictyoptera, and by others as being superfamilies (Blattoidea and Mantoidea) of the suborder Dictyoptera, in the order Orthoptera. The stick insects and their relatives are sometimes included in the Orthoptera as the suborder Cheleutoptera, and grasshoppers, crickets and katydids (Orthoptera proper, here) as the suborder Saltatoria (*see* ORTHOPTERA). Hemiptera is often split, the suborders Heteroptera and Homoptera being made orders (*see* HEMIPTERA). Megaloptera, Neuroptera and Raphidioidea are sometimes grouped together as the order Neuroptera, with two suborders Megaloptera and Planipennia (*see* NEUROPTERA).

A. Apterygota (Ametabola)

Apterygota (fig. 15) undergo no true metamorphosis; that is, they are ametabolous. The young (nymphs) closely resemble the adults except that they are smaller and sexually immature.

1. Collembola (Springtails).—Very small (usually less than $\frac{1}{8}$ in.) wingless insects with primitive chewing mouth parts, four-segmented antennae, a six-segmented abdomen with a ventral tube-like sucker on the first segment and usually a forked, springlike structure on segment four or five. They occur abundantly in moist situations, as in soil, leaf mold, rotten wood and stream banks. (*See* SPRINGTAIL.)

2. Protura (Proturans or Telsontails).—Minute (less than $\frac{1}{16}$ in.) wingless insects with sucking mouth parts and without antennae, eyes or tail filaments. The abdomen is nine-segmented in the young, twelve-segmented in the adult. Like the springtails, they prefer moist habitats and are generally found in soil and humus.

3. Diplura (Diplurans or Twintails).—Small insects (about

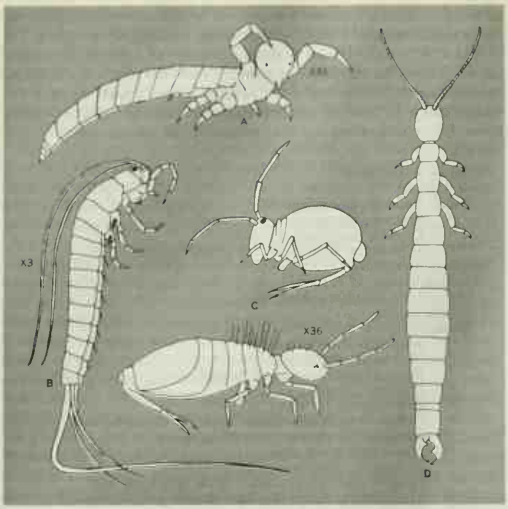


FIG. 15.—APTERYGOTA: (A) PROTURA, ACERENTOMON DODEROI. (B) THYSANURA, NESOMACHILIS MAORICUS; (C) COLLEMBOLA, (TOP) PAPIRIUS UNICOLOR, (BOTTOM) ENTOMOBRYA LAGUNA; (D) DIPLURA, EVALLJAPYX PROPINQUUS

$\frac{3}{8}$ in.) with chewing mouth parts; reduced, nonfunctional eyes (or none); and a flattened, tapering abdomen with lateral, paired tail filaments (cerci) either as long as the antennae or formed into small pincers. They are commonly found beneath the soil or among leaves and stones in moist situations. Diplurans are sometimes called two-pronged bristletails.

4. Thysanura (Bristletails, Silverfish, Etc.).—Small to medium-sized (up to $\frac{1}{2}$ in.) insects with chewing mouth parts; large eyes; long, slender, many-segmented antennae; and three long tail filaments, a median and two cerci. They are fast runners found in the soil, but some species (silverfish, firebrats) are common indoors in northern climates. *See* APTERYGOTA; SILVERFISH.

B. PTERYGOTA (PROMETABOLA)

All pterygotans undergo metamorphosis, either slight and incomplete (Prometabola and Hemimetabola) or pronounced and complete (Holometabola).

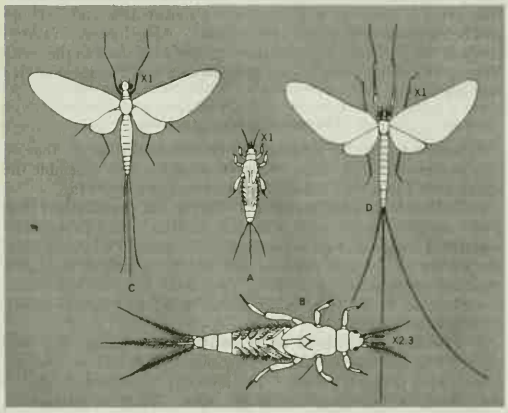

FIG. 16.—EPHEMEROPTERA, MAY FLIES. EPHEMERA. (A,B) NYMPHS SHOWING EXTERNAL WING-PADS AND LATERAL ABDOMINAL GILLS; (C) SUBIMAGO, THE WINGED LARVAL STAGE; (D) IMAGO OR ADULT

Ephemeroptera (May Flies) (Fig. 16).—Small to medium-sized (up to $1\frac{1}{2}$ in.), soft-bodied, winged insects with large eyes, vestigial mouth parts, inconspicuous bristlelike antennae, slender legs, long, segmented cerci and usually a median caudal filament; the wings are many-veined and fanlike, the second pair reduced or lacking; the nymphs are aquatic, with biting mouth parts, external wing pads and lateral abdominal gills (in some cases on the head or thorax also). A sexually immature, nonfeeding, subimago stage, with functional wings, is followed by a short-lived adult stage. *See* MAY FLY.

C. PTERYGOTA (HEMIMETABOLA)

1. Odonata (Dragonflies, Damsel Flies) (Fig. 17).—Large insects (wingspread up to $4\frac{1}{2}$ in.) with a long, slender body; large eyes; very short antennae; biting mouth parts; and two pairs of membranous, net-veined wings. Males have a secondary copulatory organ on second (or second and third) abdominal segments. The nymphs are aquatic, with a long, hinged prey-grasping labium (the "mask"); rectal respiration is replaced in later nymphal stages of damsel flies by three caudal gills. (*See* DRAGONFLY.)

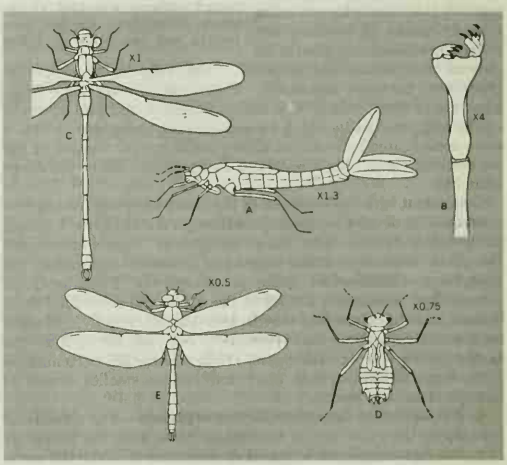

FIG. 17.—ODONATA, SUBORDER ZYGOPTERA. ARCHILESTES CALIFORNICA: (A) NYMPH WITH THREE CAUDAL GILLS; (B) PREHENSILE LIP OF NYMPH SHOWING LABIAL PALPS EVOLVED INTO RAPTORIAL JAWS; (C) IMAGO. ODONATA, SUBORDER ANISOPTERA. SOMATOCHLORA METALLICA: (D) NYMPH; (E) IMAGO

2. Blattaria (Cockroaches) (Fig. 18).—Medium-sized to large ($\frac{3}{8}$–$2\frac{3}{8}$ in.), ovoid, flattened insects with well-developed eyes; long slender antennae; chewing mouth parts; a large pronotum; and abdominal cerci. The wings, when present and fully developed, are many-veined, the fore pair narrower and thicker than the hind pair. The nymphs are terrestrial, resembling the adults in general form. (*See* COCKROACH.)

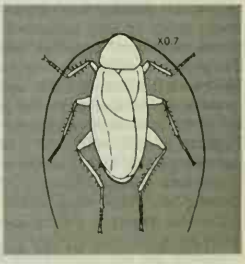

FIG. 18.—BLATTARIA. PERIPLANETA AMERICANA, COCKROACH

3. Mantodea (Mantids).—Medium-sized to large (up to and exceeding 4 in.) predaceous insects with a large head; well-developed eyes; an elongated prothorax; and very large, spined, grasping front legs held in a prayerlike attitude when at rest. The wings, when present and fully developed, are four, the first pair narrow, the second large and fanlike. The nymphs are terrestrial and similar to the adults. (*See* MANTIS.)

4. Phasmida (Stick Insects) (Fig. 19).—Large (up to 13 in.),

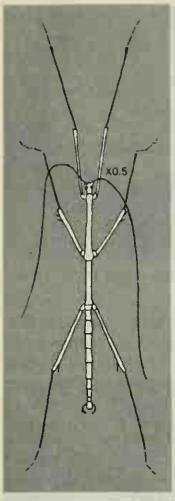

FIG. 19.—PHASMIDA. DIAPHEROMERA FEMORATA, WALKING STICK

sticklike or leaflike, plant-eating insects with small eyes; long, slender antennae; and chewing mouth parts. The nymphs are terrestrial and similar to the adults in habits and general form. (*See* STICK INSECT; LEAF INSECT.)

5. Isoptera (Termites) (Fig. 20).—Small to medium-sized (queens up to 3½ in.) social insects, living in large colonies made up mostly of pale, soft-bodied, immature workers of both sexes. Reproductive forms usually pigmented, with two pairs of similar-shaped wings that are shed after mating and dispersal flights. (*See* TERMITE; SOCIAL INSECTS.)

6. Dermaptera (Earwigs) (Fig. 21).—Medium-sized (up to and exceeding 1½ in.), elongate, tough-bodied, omnivorous insects with chewing mouth parts; large eyes; long antennae; and a pair of forcepslike cerci at the tip of the abdomen. The wings, when present and fully developed, consist of a fanlike second pair that fold up under short, padlike wing covers modified from the first pair. The nymphs are similar to adults in habits and general form. (*See* EARWIG.)

7. Orthoptera (Grasshoppers, Crickets, Katydids) (Fig. 22).—Medium-sized to large (up to and exceeding 4 in.) plant-eating insects with a large head; chewing mouth parts; and the pronotum and hind legs usually enlarged for jumping. The wings, when present and fully developed, consist of a large, fanlike second pair that fold under a narrow, elongate, leathery first pair (tegmina). The

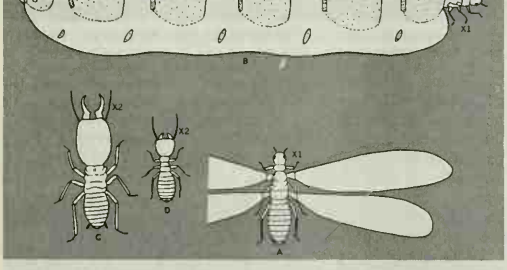

FIG. 20.—ISOPTERA, TERMITES OR WHITE ANTS. TERMES NATALENSIS: (A) WINGED VIRGIN QUEEN (MALE SIMILAR IN APPEARANCE AND SIZE); (B) AGED QUEEN (MINUS WINGS) WITH ABDOMEN DISTENDED WITH EGGS; (C) SOLDIER; (D) WORKER

nymphs are similar to the adults in habits and general form. (*See* ORTHOPTERA; CRICKET; KATYDID; GRASSHOPPER; LOCUST.)

8. Embioptera (Embiids or Web Spinners) (Fig. 23).—Small (usually less than ½ in.), elongate, flattened, semisocial plant-eating insects with chewing mouth parts; well-developed eyes; elongate and many-segmented antennae; and enlarged front tarsi modified into glands that spin the silk used in lining the tunnels in which they live. The two pairs of wings are narrow, similar and present in the male only. The nymphs are terrestrial, occurring with the adults and resembling them in habits and general body form. (*See* EMBIOPTERA.)

9. Plecoptera (Stone Flies) (Fig. 24).—Medium-sized to large (½–2½ in.), elongate insects with chewing mouth parts (often reduced); well-developed eyes; long, many-segmented antennae; abdominal cerci; and usually two pairs of well-developed, similarly textured wings, the fore pair narrower than the hind pair. The

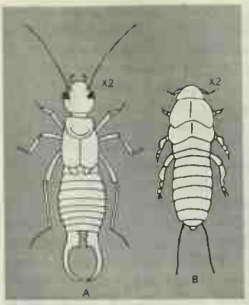

FIG. 21.—DERMAPTERA, EARWIGS: (A) FORFICULA AURICULARIS, EUROPEAN EARWIG; (B) HEMIMERUS TALPOIDES, LOUSELIKE EXTERNAL PARASITE OF AFRICAN RATS

nymphs are aquatic, with body proportions as in the adult. (*See* STONE FLY.)

10. Zoraptera (Zorapterans) (Fig. 25).—Minute (less than ⅛ in.), rare, semisocial insects with chewing mouth parts; long antennae of nine segments; and single, segmented cerci. Adults may be winged or wingless. In the latter case they are also eyeless. The wings are delicate, membranous, with only one or two veins, and are shed after mating and dispersal. The nymphs are terrestrial and similar to the adults.

11. Psocoptera or Corrodentia (Book and Bark Lice) (Fig. 26).—Minute to small (up to and exceeding ¼ in.), compact insects with a large head; chewing mouth parts; many-segmented antennae; a very narrow prothorax; and no cerci. The wings, when present and fully developed, are similar in texture, with simple, reduced venation, the front pair being larger than the hind pair. The nymphs resemble the adults. (*See* PSOCOPTERA.)

12. Mallophaga (Biting Lice) (Fig. 27).—Minute to small (up to ¼ in.), secondarily wingless ectoparasites, living largely on birds, with chewing mouth parts; and reduced eyes and antennae. The nymphs resemble the adults and because there are no wings, undergo no evident metamorphosis. (*See* LOUSE; MALLOPHAGA.)

13. Anoplura (Sucking Lice) (Fig. 28).—Minute to small (up to ¼ in.), secondarily wingless, blood-sucking ectoparasites, living largely on mammals. They are similar in form to biting lice but have piercing rather than chewing mouth parts. There is no evident metamorphosis. (*See* ANOPLURA.)

14. Thysanoptera (Thrips) (Fig. 29).—Minute (less than $\frac{1}{16}$ in.), slender insects with conelike piercing and lacerating mouth parts; large eyes; one- or two-segmented tarsi with a bladderlike tip; and no cerci. Wings, when present and fully developed, are long, narrow and fringed with hair. The nymphs are plant-eating or predaceous and resemble the adults. Unlike most other insects with incomplete metamorphosis, they have a pupalike stage.

15. Hemiptera (True Bugs, Etc.).—Minute to large (up to 4½ in.) insects of very diverse form but having beaklike, plant-piercing or blood-sucking mouth parts and incomplete metamorphosis. Wings are usually present and the compound eyes are usually large. The group divides into two major sections here treated as suborders but regarded by some as orders.

Suborder Homoptera (Cicadas, Treehoppers, Leafhoppers, Aphids, Scale Insects, Etc.) (Fig. 30).—Sap-sucking insects. Wings, if present, are membranous, with fore and hind pair similar and held sloping and rooflike over the body. When feeding they discharge a sweet fluid, honeydew, utilized as food by ants, bees and wasps. The more primitive forms are the larger (cicadas, treehoppers) and have short, bristlelike antennae and sawlike ovipositors; the more specialized are the smaller (aphids, mealy bugs, scale insects) and have either stout or long threadlike antennae at some stage in development. The aphids in particular have complex lifecycles that may involve alternation of host plants and alternation of generations with extreme polymorphism.

FIG. 22.—ORTHOPTERA: (A) OECANTHUS NIGRICORNIS, TREE CRICKET; (B) TRIDACTYLUS APICAL PYGMY CRICKET

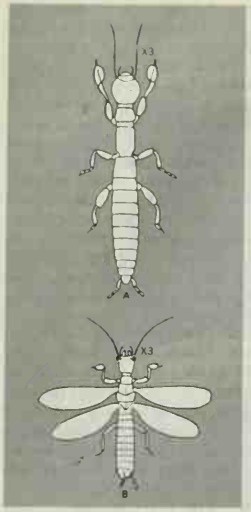

FIG. 23.—EMBIOPTERA, WEB SPINNERS, SMALL SEMISOCIAL TROPICAL GROUP. EMBIA MAJOR: (A) FEMALE; (B) MALE

Suborder Heteroptera (*True Bugs*) (*Fig. 31*).—Insects with antennae four- or five-segmented. Wings, if present, are held flat over the body with the tips overlapping, the fore pair thickened at the base. The nymphs and adults are usually similar in form and have similar food habits, many being predaceous or bloodsucking, others imbibing plant juices. Some live in the water (backswimmers, water boatmen, giant water bugs) or on the surface of the water (water striders); a few are semiaquatic (shore bugs); the remainder, terrestrial. Bloodsuckers include the assassin bugs and bedbugs; plant juice feeders include the stink bugs, plant bugs, squash bugs, lace bugs, etc. *See* HEMIPTERA; CICADA; APHID; BEDBUG; WATER BOATMAN; etc.

D. PTERYGOTA (HOLOMETABOLA)

1. Coleoptera (Beetles, Weevils) (Fig. 32).—Minute to very large (up to and exceeding 6 in.) insects, usually hard-shelled and winged. The fore pair of wings (elytra), thickened and horny, meet in a straight line down the back; the hind pair, if present, larger, membranous and folded beneath the fore wings; chewing mouth parts well developed.

The suborder Adephaga, with terrestrial, aquatic or shore-loving groups, contains the most generalized beetles, with campodeiform larvae, *i.e.*, active and predaceous. Most remaining beetles are grouped in the suborder Polyphaga, which contains several radiating lines of evolution. These lines arise with forms generally having campodeiform larvae and end with forms having cylindrical or even legless grublike larvae. In some higher families, the first stage larva is active and campodeiform, but the fullgrown larva is cylindrical and nearly legless. This ontogeny suggests a recapitulation of ancestral forms.

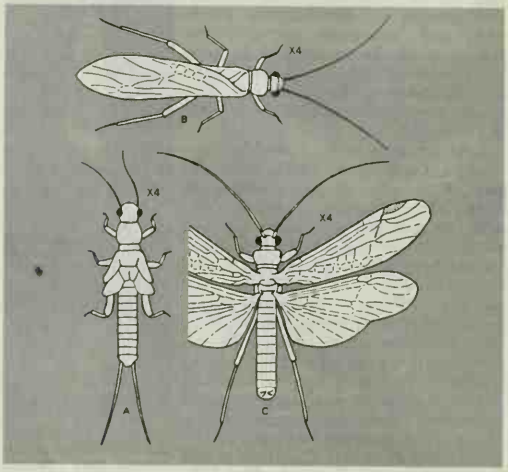

FIG. 24.—PLECOPTERA, STONE FLIES. NEMOURA VALLICULARIA: (A) NYMPH; (B,C) IMAGOES

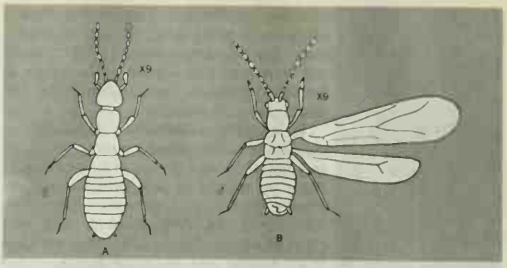

FIG. 25.—ZORAPTERA, RARE, SEMISOCIAL TERMITELIKE INSECTS. ZOROTYPUS HUBBARDI: (A) FEMALE; (B) MALE

Larvae of many of the higher groups are able to dispense with legs because (1) they live in the interior of plants; (2) are parasitic on other insects; or (3) have evolved toward a social life, like the

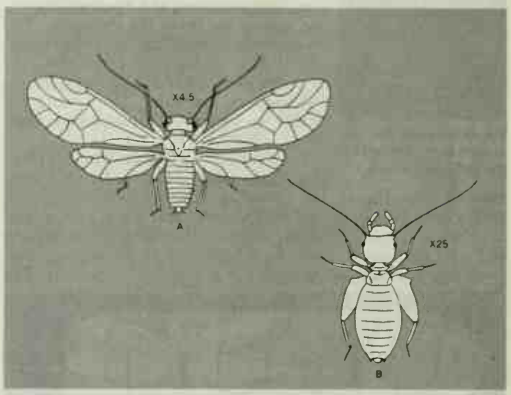

FIG. 26.—CORRODENTIA: (A) PSOCUS FASCIATUS, PSOCID; (B) LIPOCELIS DIVINITORIA, BOOK LOUSE

tumblebugs of the Scarabaeoidea and the ambrosia beetles of the Scolytidae. Metamorphosis is complete; hypermetamorphosis occurs in the Meloidae, as, for example, *Epicauta vittata* and *E. cinerea*, which are predators on clusters of grasshopper eggs. Plant parasitism occurs throughout the higher families of the Coleoptera, especially in long-horned beetles, leaf beetles, bark beetles and weevils. In these groups, many species are obligate parasites and are limited to feeding on one species of plant. As a result, many are serious pests of forest or agricultural crops.

In the family Platypodidae and in some genera of the Scolytidae, food habits have shifted from that of eating general plant tissues in which tunnels lie, to the cultivation and eating of fungi grown on the wood walls of the tunnels. The fungal food is tended by the mother, as it needs special care in planting and harvesting to prevent fast growth, which sometimes chokes the tunnels and smothers the family. The mother carries live fungus from her home burrow to that which she makes for her eggs and young. After establishing fungus beds in the burrow, she gathers the crop and places it before the larvae. (*See* BEETLE.)

2. Strepsiptera (Twisted-Wing Insects) (Fig. 33).—Uncommon minute to small (less than $\frac{3}{16}$ in.) insects showing extreme sexual dimorphism, the male being winged and active, the

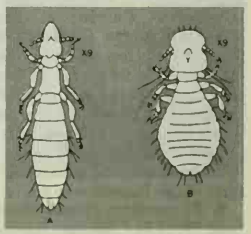

FIG. 27.—MALLOPHAGA, BITING OR BIRD LICE: (A) LIPEURUS SQUALIDUS, DUCK LOUSE; (B) GONIOCOTES COMPAR, PIGEON LOUSE

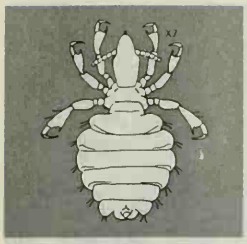

FIG. 28.—ANOPLURA, SUCKING OR MAMMALIAN LICE. HEMATOPINUS SUIS, HOG LOUSE

female usually being a degenerate endoparasite. As primary larvae both males and females are free, active, spiny and long-legged; however, after boring into the abdomen of a host (mostly Homoptera and Hymenoptera) the males develop in the usual manner but the females become literally egg-producing sacs without eyes, antennae or legs. Males have eyes wide apart, in some species stalked; forewings reduced to short flaps (pseudohalteres); thorax large; and abdomen short.

The male pupates in the last larval skin within the host. The female larva changes into a pupa with head and thorax fused, from which form she develops no further; at maturity she is enclosed in the larval skin, at the anterior end of which is a brood-passage opening, which is also used by the male in coitus. In the most primitive family, Mengeidae, the female has small eyes, antennae, mouth parts and short legs, and has been found living free under stones. In all higher families, however, she is an endoparasite, feeding off her host by osmosis.

There is much evidence to support the view that the Strepsiptera are actually a highly specialized family (Stylopidae) of parasitic Coleoptera. The forewings of the male appear to be rudimentary elytra. The life history, habits and structure of the larvae somewhat parallel those in the Rhipiphoridae (Coleoptera). In both, the primary larva is active and the later larva becomes an endoparasite.

3. Megaloptera (Dobson Flies, Alder Flies).—Large (up to about 5 in.) terrestrial insects with aquatic larvae and complete metamorphosis. The adults are similar, having two pairs of large membranous wings with numerous veins and cross-veins; large eyes; long antennae; and chewing mouth parts. The larvae also have chewing mouth parts and are predaceous on small aquatic animals in lakes and streams. When ready to pupate, they leave the water and transform into adults in cells constructed in moist soil or decomposing wood. (*See* ALDER FLY; DOBSON FLY.)

4. Neuroptera (Ant Lions, Lacewings, Mantispids, Etc.) (Fig. 34).—Small to large (wingspread up to $2\frac{3}{4}$ in.) soft-bodied insects with long, subequal, net-veined wings, which are folded rooflike over the body (venation is dense and elaborate in the higher forms); five-jointed tarsi; mouth parts with raptorial jaws, usually modified into tubular blood-sucking organs; and no cerci.

(M,N,O,P) ALEYRODES CITRI, CITRUS WHITE FLY: (M) "PREPUPA"; (N) MALE "PUPA"; (O) MALE; (P) FEMALE

Metamorphosis is complete, hypermetamorphosis occurring in the Mantispidae. Larvae various, being campodeiform or eruciform, and gilled in the aquatic Sisyridae. A cocoon is spun from silk produced by the Malpighian tubules. Structure and habits are very different from family to family. They show evolution from a fairly simple venation, as in the Sialidae and Coniopterygidae, to some of the most elaborately veined wings known, in such families as the Myrmeleonidae, Ascalaphidae and Dilaridae.

The majority are voracious wandering predators that stalk their prey, but the larva of the ant lion, Myrmeleonidae, digs a circular pit in sand or dust in which it lies in wait for any insect that slides to the pit bottom. The larva of the spongilla fly (Sisyridae) is parasitic in fresh-water sponges, while that of the Mantispidae is parasitic in egg sacs of spiders where it undergoes a hypermetamorphosis. The lacewings of the Hemerobiidae and Chrysopidae eat aphids and scale insects, making themselves very beneficial insects. (*See* NEUROPTERA; ANT LION; LACEWING FLY.)

5. Raphidioidea (Snake Flies).—Medium-sized to large (up to and exceeding 1 in.) insects with two pairs of similar, net-veined wings; long antennae; chewing mouth parts; a long, serpentlike neck and large eyes. The female has a long, slender, curved ovipositor. Metamorphosis is complete. The larvae are terrestrial and predaceous, with a well-developed head, strong thoracic legs and segmented antennae. Two families are known, the Raphidiidae, which have simple eyes (ocelli) in addition to the compound eyes, and the Inocelliidae, which lack ocelli.

6. Mecoptera (Scorpion Flies) (Fig. 35).—Small to medium-sized (usually $\frac{1}{2}$–1 in.), slender, predaceous insects with chewing mouth parts; large eyes; long antennae; long, slender legs. Wings, when present, are four and long and slender. Metamorphosis is

complete, the larvae being eruciform.

The common forms of damp woods, *Panorpa* and *Bittacus*, look like four-winged crane flies (Diptera). The venation of the wings is similar to that of the crane flies, but with more cross veins. The name comes from the great bulb of male genitalia in some genera, appearing as the stinging organ on the tail of a scorpion. The caterpillarlike larva is a voracious predator that wanders among the dead leaves of the forest floor. The adult *Bittacus* hangs from bushes by the long fore legs and catches passing gnats, etc., with the grasping hind feet. This requires remarkable binocular vision to the rear, very unusual in animals.

Mecoptera are of special interest to students of insect evolution since they appear to be close to the ancestral group from which evolved the panorpid or mecopteroid complex: the orders Mecoptera, Trichoptera, Lepidoptera, Diptera and Siphonaptera. The Neuroptera are also close relatives. (*See* SCORPION FLY.)

7. Trichoptera (Caddis Flies) (Fig. 36).—Small to medium-sized (less than 1 in.) mothlike insects, nocturnal or crepuscular, with feeble chewing mouth parts; long antennae; large eyes; and the wings covered with hairs and scales and folded rooflike over the body. Metamorphosis is complete. The larvae are aquatic, living in a silk case to which usually are attached sand grains, sticks or pebbles; eruciform; and in most species have filamentous abdominal gills.

Caddis flies are general feeders, though some are restricted to a vegetarian diet. The tubes or cases may be free so the larvae can crawl about by extending head and legs or may be attached solidly to a rock or log in the stream bed. They pupate in a silk or gelatinous cocoon within the case. The pupa has no gills but breathes the air dissolved in the water. When ready to emerge, the pupa chews its way out by means of its special free jaws, the pupal skin splits and the adult flies up from the water. Incapable of feeding because of defective mouth parts, the adult lives only long enough to mate and oviposit, and then dies. (*See* CADDIS FLY.)

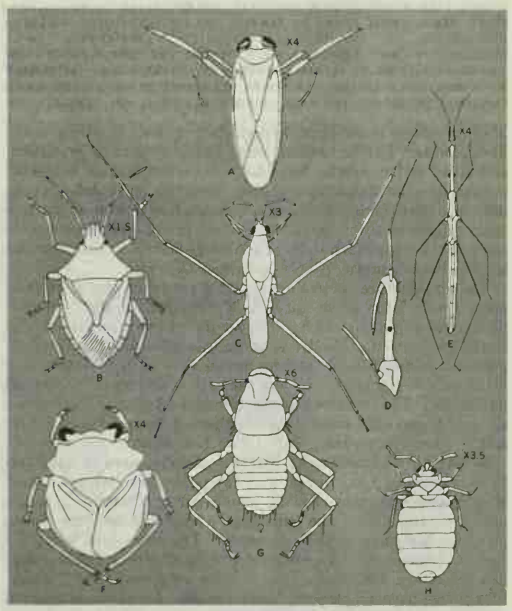

FIG. 31.—HEMIPTERA, SUBORDER HETEROPTERA, TRUE BUGS: (A) ARCTOCORIXA ALTERNATA, WATER BOATMAN; (B) APATETICUS CYNICUS, STINK BUG; (C) GERRIS BUENOI, WATER STRIDER; (D,E) HYDROMETRA MARTINI; (D) SIDE VIEW OF HEAD SHOWING PIERCING BEAK; (F) GELASTOCORIS BARBERI, TOAD BUG; (G) HESPEROCTENES IMPRESSUS, PARASITIC ON BATS; (H) CIMEX LECTULARIUS, BEDBUG

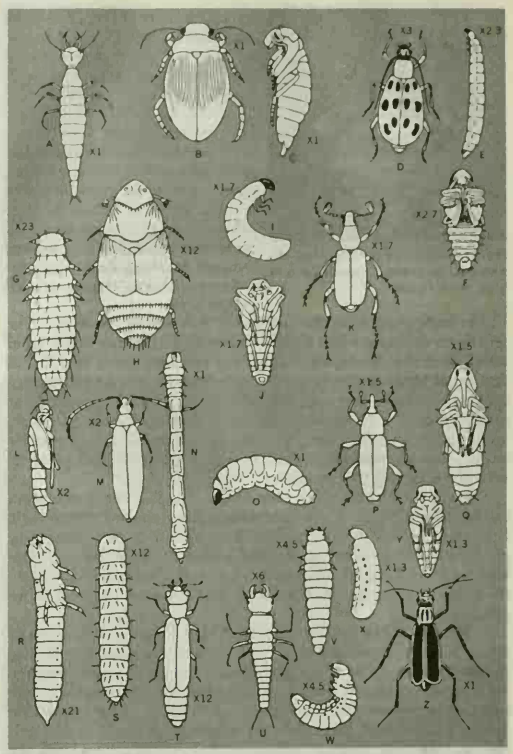

FIG. 32.—COLEOPTERA, BEETLES—LARVAL, PUPAL AND ADULT STAGES: (A–C) DYTISCUS MARGINALIS, DYTISCID, DIVING BEETLE; (D–F) DIABROTICA 12-PUNCTATA, CHRISOMELID, CORN ROOTWORM; (G,H) PLATYPSYLLUS CASTORIS, PLATYPSYLLID, PARASITIC ON THE BEAVER; (I–K) MACRODACTYLUS SUBSPINOSUS, SCARABAEID, ROSE CHAFER; (L–N) CUPES CONOCOLOR, CUPESCID, PRIMITIVE WOOD BORER; (O–Q) SPHENOPHORUS OBSCURUS, WEEVIL, SUGAR CANE BORER; (R–T) MICROMALTHUS DEBILIS, MICROMALTHID, LEGGED AND LEGLESS LARVAE, PRIMITIVE BORER; (U–Z) EPICAUTA, BLISTER BEETLES, PARASITIC ON GRASSHOPPER EGGS

8. Lepidoptera (Butterflies, Moths) (Fig. 37).—Small to large (wingspread up to and exceeding 6 in.) insects usually without mandibles; with two maxillae and galeae developed into a hollow nectar-sucking proboscis, coiled at rest; and wings usually prominent, fanlike and covered with overlapping scales. Metamorphosis is complete. The larvae are caterpillars with up to four pairs of abdominal prolegs; compound eyes reduced to a semicircle of 4–12 ocelli on each side of the head; vestigial antennae; and chewing mouth parts. The butterflies have thickened antennae, usually clubbed at the tip but sometimes hooked (skippers, Hesperoidea); they are active during the day. The moths have many-jointed antennae, often featherlike but never clubbed. Moths are usually drab and crepuscular or nocturnal, though there are some brightly-coloured forms that are diurnal and have the appearance and habits of large butterflies.

The caterpillars are herbivorous, except in a few butterflies (Lycaenidae) that feed on aphids and other small insects, and some carnivorous moth larvae. A few are borers in plant stems and wood; others are aquatic, with filamentous gills. The adults usually feed on nectar, injured fruits, etc., imbibing the juices.

Except in the very primitive Micropterigidae, the pupa is obtect, with all appendages glued to its surface, one of the highest forms of pupa known. The last instar of moth caterpillars usually spins a silk cocoon that serves as a protective case during pupation. The butterfly caterpillars have no silk cocoon, but the pupa (chrys-

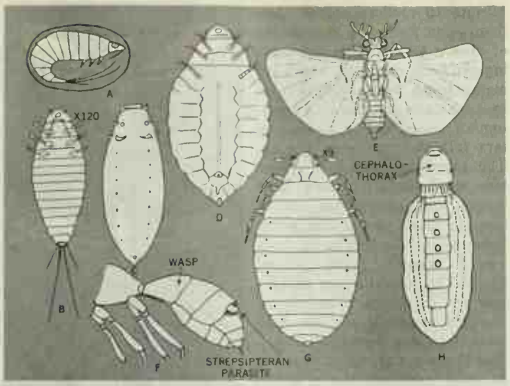

FIG. 33.—STREPSIPTERA, TWISTED-WINGED INSECTS, INTERNAL PARASITES OF OTHER INSECTS. alis) hangs with a silken loop about its middle. The oriental silkworm or silk moth (*Bombyx mori*) is the only insect fully domesticated by man. It cannot live without his care in daily feeding and is not known in a wild form (*see* SILK).

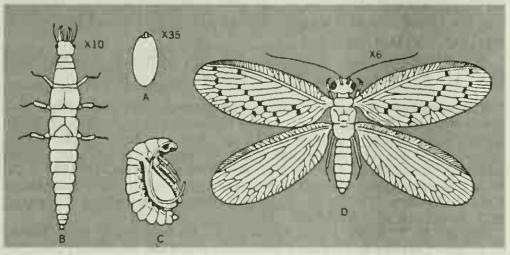

FIG. 34.—NEUROPTERA, NETTED-WINGED FLIES. HEMEROBIUS STIGMATERUS, LACEWING: (A) EGG; (B) LARVA; (C) PUPA; (D) ADULT

Adaptive coloration and mimicry are highly developed in these large and conspicuous insects. Many caterpillars also exhibit protective coloration. (*See* BUTTERFLY AND MOTH; MIMICRY.)

9. Diptera (True Flies) (Fig. 38).—Minute to large (less than $\frac{1}{16}$ in. up to 2 in.) insects with large antennae and eyes; mouth parts modified for sucking and lapping; the first pair of wings, on mesothorax, well developed, the second pair being reduced to knobs (halteres) and present even when fore wings are absent.

Flies divide into Nematocera, with whiplike antennae, and Brachycera, with short antennae, though each group has some exceptions. Nematocera include many primitive families like crane flies (Tipulidae), which are elongate and slow-flying. Larvae of Nematocera usually have a well-developed head, with mandibles that can be opposed to each other; pupae are obtect, with the adult

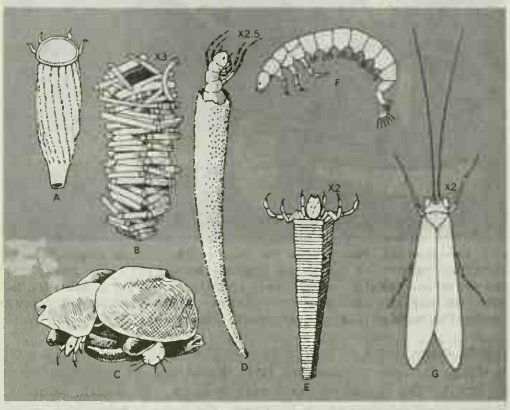

FIG. 36.—TRICHOPTERA, CADDIS FLIES AND CASEWORMS. (E) CHIMNEY CASE OF BRACHYCENTRUS NUMEROSUS. (F,G) HYDROPSYCHE SIMULANS: (F) WEB-SPINNING LARVA; (G) IMAGO

appendages visible, but stuck down. Brachycera divide again into Orthorrhapha, which have many features in common with Nematocera; and Cyclorrhapha, which are the shorter, stumpier flies, often bristly, like bluebottles, fruit flies and hover flies. Larvae of Cyclorrhapha are maggots or grubs, with no distinct head; mouth-hooks working vertically, and usually two spiracles posteriorly; pupae are formed within the hardened skin of the previous larval stage, called a puparium. In the Orthorrhapha (straight seam) the adult escapes from a straight, longitudinal dorsal slit. In the Cyclorrhapha (circular seam) the anterior end of the pupal case opens by a circular seam.

Larvae of flies have adapted themselves to an extraordinary range of food-materials, perhaps greater than those of any other order of insects. A great many feed in decaying vegetable materials, leaf-mold, rotting wood or fungi. Some attack healthy

plants, mine stems of leaves or provoke plant galls; others feed in dung, carrion, wounds and fetid discharges, or suck the blood or destroy the tissues of vertebrate animals. In several families, loosely grouped together as Pupipara, the larva is nourished on internal secretions by the mother until it is ready to pupate.

Many families of flies are parasitic, as larvae, on other insects. The Tachinidae are one of the most beneficial groups of insects. In some cases the egg is laid on caterpillars, back of the head. The maggot bores in but leaves its posterior end, which has the spiracles for breathing, projecting from the host's body, or it may attach the spiracular end to a large trachea or spiracle of the host while it devours the viscera. The maggots of other flies help to reduce the carcasses of birds, mammals and dead fish to soil.

The housefly (*q.v.*), whose maggot is reared in filth and excrement, may spread disease organisms when it walks on human food. The many blood-sucking flies, from the mosquito (*q.v.*) to the horse- and tsetse fly (*q.v.*), add to the discomfort of man and his domestic animals. The mosquitoes that transmit malaria, yellow fever and other diseases create serious health problems over large areas. (*See* FLY.)

10. Siphonaptera (Fleas) (Fig. 39).—Small (less than $\frac{1}{4}$ in.) insects, secondarily wingless, with laterally compressed bodies; piercing and sucking mouth parts; long, spiny legs and short, clubbed antennae. The adults feed on the blood of mammals and birds, and a number of species are involved in the transmission of disease organisms. Metamorphosis is complete. The larvae are slender and wormlike, with long body hairs; no legs; and small, chewing mouth parts. They are scavengers, living in the soil or in the nest debris of their hosts. When larval development is complete, they spin a cocoon in which they pupate and transform to the adult. (*See* FLEA.)

11. Hymenoptera (Ants, Bees, Wasps, etc.) (Fig. 40).—Minute to moderate-sized (less than $\frac{1}{32}$ in. up to $4\frac{1}{2}$ in.) insects of diverse form but usually having two pairs of wings, which are membranous and often divided by a network of veins into a system of closed cells. Hymenoptera fall into two great groups. The primitive Symphyta (sawflies, wood wasps, horntails) have larvae like caterpillars, which damage many plants, and sometimes bore into trunks of trees (wood wasps). The second group, the Apocrita, are divided into the Parasitica (ichneumons, chalcids, cynipids) and the Aculeata (stinging hymenopterans). The Parasitica are usually minute to small, and their larvae live as internal parasites (or parasitoids) in the eggs, larvae and pupae of other insects. The gall wasps, Cynipoidea, either provoke plant galls or live in the galls made by other insects. The Aculeata comprise the bees, wasps and ants. Their larvae are helpless, soft-bodied grubs that receive varying degrees of maternal care, from being supplied with a store of food to being given continuous attention in the well-organized nests of the ants and the social bees and wasps. For an account of social Hymenoptera, *see* SOCIAL INSECTS.

INSECT, SOCIAL: *see* SOCIAL INSECTS.

INSECT BITES AND STINGS. Malaria, yellow fever, typhus, encephalitis, tularemia, bubonic plague, typhoid fever, anthrax and many other diseases are carried and transmitted by insects. This article, however, concerns itself primarily with host reactions resulting from toxins peculiar to the insect itself and with measures for repelling these insects and treating the diseases that their bites provoke.

Fortunately, few of the billions of insect bites and stings that the population of the world suffers each year result in serious disease. Most insect bites, such as those of the fly, mosquito and flea, cause an almost immediate reaction in humans consisting of itching, redness and local swelling of the skin. This usually subsides within 2 to 24 hours without leaving any permanent mark. It is believed that this result is an allergic reaction dependent upon salivary components to which the host has developed a sensitivity via previous exposure. Infants receiving their first mosquito bite show no reaction (sensitivity) to the bite, and individuals who receive bites continually over long periods of time may develop an immunity (desensitization) and consequently develop no reaction to the insect bite. Thus, natives frequently hold the erroneous belief that parasites indigenous to the region do not bite them.

Stinging insects such as the bee, hornet or wasp give rise to intensely painful, elevated skin lesions that are transitory and believed to be due to the irritant action of formic acid and an alkaline neurotoxic substance present in the venom. Multiple stings may give rise to alarming systemic illness with fainting, collapse of the circulatory system, difficult breathing and, in rare instances, death. The honeybee leaves its stinger in the skin whereas the wasp does not. Beekeepers eventually develop an immunity to the sting of the bee and they may receive many stings without experiencing any subjective or objective response. Such an immunity can be developed experimentally by repeated injections of bee venom.

Bloodsucking lice (Anoplura) live on or close to the skin and occur in three varieties: the head louse, body louse and pubic louse. They fix their eggs to hair or clothing and periodically feed on their host. Their bites result in severely itchy skin lesions, which when scratched frequently become infected and may thus result in widespread complications.

Bedbugs, which live in mattresses, walls and furniture, attack their host only in the dark. Though they are usually thought of as denizens of poverty and filth, they not infrequently find their way into the environs of affluence.

In way of treatment, local applications for any bite or sting are of little value other than the removal of insect parts left in the wound or local applications of antiseptic agents to prevent infection. Anti-itch medicines such as menthol or phenol compounds may be applied. For those insects such as lice that reside on the skin, local applications of Cuprex, DDT powder or lindane will destroy the insects. However, some insecticides such as DDT are not lethal for the eggs of these insects so that repeated applications over two weeks are necessary to eradicate the colony. Spraying the environs with DDT, chlordan or lindane is usually effective in destroying resident bedbugs, fleas and most other insects.

Much more fiction than fact surrounds the question of effective insect repellents. So-called oral repellents (compounds believed to repel insects after being taken orally by an individual) have not been proved of value for the human. However, local applications to the skin of such compounds as dimethyl phthalate, dimethyl carbate, butopyronoxyl and 2-ethyl-1,3-hexane-diol either alone or in combination have been shown to be very effective for general use. A good, all-purpose, clothing repellent for mosquitoes, ticks, fleas and chiggers is the following mixture: *n*-butyl acetanilide, 30%; benzyl benzoate, 30%; 2-butyl-2-ethyl-1,3-propanediol, 30%; and polysorbate 80, 10%. This mixture is diluted in one to two parts of water.

See also ENTOMOLOGY: *Applied Entomology: Medical and Veterinary Entomology.* (RD. B. S.)

INSECTICIDES, chemicals used for destroying insect pests. When employed to protect plants, they may be applied in the form of sprays, aerosols or as dusts. Insects indoors may be killed by fumigation (*q.v.*). *See* PEST CONTROL; ENTOMOLOGY: *Applied Entomology: Principles of Insect Control*; SPRAYS AND DUSTS IN AGRICULTURE; and also references under "Insecticides" in the Index.

INSECTIVORE, a name loosely applied to any insect-eating animal or plant, but more specifically given to any of the mammals of the order Insectivora, which includes shrews, moles, hedgehogs, tenrecs, solenodons and extinct forms that date from the very beginnings of placental mammalian history. Insectivores are common throughout the temperate and tropical zones of Europe, Asia, Africa and North America. Only one genus occurs in South America, and none in Australia or the polar regions. The greatest diversity is seen among the African forms. Insectivores include the smallest and most active of mammals. They are chiefly insect eaters, but some also feed on other small animals, including mice, snakes and birds, and even on plants. Most are small mouselike forms that are burrowers or tree dwellers; a few are adapted for swimming. Except for the tree shrews, all are at least partly nocturnal.

GENERAL

Living insectivores fall into four well-defined groups: (1) the jumping or elephant shrews (Macroscelididae) and tree shrews (Tupaiidae); (2) spiny and hairy hedgehogs (Erinaceidae); (3) true shrews (Soricidae); and (4) tenrecs, potamogales (Tenrecidae) and golden moles (Chrysochloridae). The first group is the most primitive in structure and is generally treated as a suborder, the Menotyphla. Some authorities regard the Menotyphla as a distinct order, while others classify the tree shrews as a suborder of Primates (*q.v.*) and the jumping shrews as a suborder of Insectivora.

The remaining three groups of living insectivores are fairly homogenous in basic characters and are classified as the suborder Lipotyphla. The hedgehog group appears to be the most primitive of the Lipotyphla and the ancestral stock of the rest of the suborder.

Characteristic Features.—Insectivores range in size from the pygmy shrew (*Suncus etruscus*) of southern Europe, which weighs as little as two grams and measures one and one-half inches in combined head and body length, to the comparative giant, the *bulau* or moonrat (*Echinosorex gymnurus*), a hairy hedgehog of Borneo, which attains a length of 15 in. or more. The snout of insectivores is typically elongate and pointed, or provided with tentacles as in some moles; the tail is well developed except in most burrowing forms; fore and hind feet are provided with four or five toes, the first toe never being opposable. Most insectivores possess the primitive number of teeth for placental mammals, which may be expressed by the following formula showing the number of each kind of tooth in each upper and lower jaw of one side: incisors $\frac{3}{3}$; canines $\frac{1}{1}$; premolars $\frac{4}{4}$; molars $\frac{3}{3} = 22$, or a total of 44 teeth. Sometimes a fourth pair of molars is present, while the incisors may be reduced to two in each upper jaw and one in each lower jaw. Canines are usually weak and, in many insectivores, not clearly differentiated from incisors and first premolars. Molar crowns may have (1) three main tubercles in the shape of a V (zalambdodont), (2) five tubercles in the shape of a W (dilambdodont), or (3) four tubercles intermediate in shape.

The skull is generally elongate, with the tympanic bone ringlike and free, enclosed in the tympanic cavity or included in the formation of the tympanic bullae. The clavicle is usually present, except in the otterlike *Potomogale*, and the entepicondylar foramen and central wrist bone are generally present. The cerebral hemispheres of the brain are smooth and do not extend backward over the cerebellum.

Jumping shrews and tree shrews (Menotyphla) are distinguished from all other insectivores (Lipotyphla) by the presence of a pouch (caecum) off the digestive tract. The uterus is two-horned,

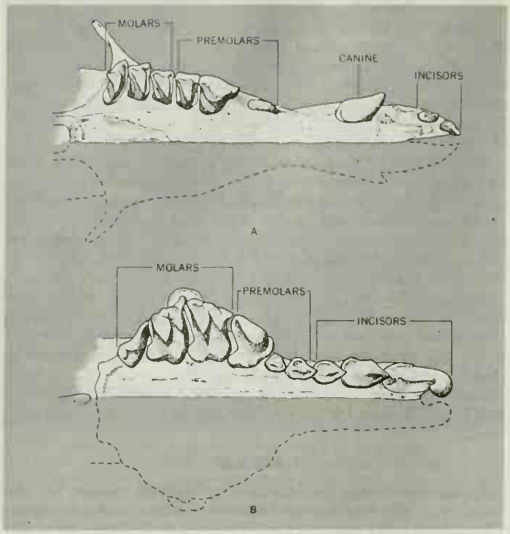

FIG. 1.—DENTITION OF INSECTIVORES ILLUSTRATING THE TWO PRINCIPAL TYPES OF MOLAR TEETH: (A) ZALAMBDODONT OR V-SHAPED MOLARS IN A TENREC (TENREC EDAUDATUS); (B) DILAMBDODONT OR W-SHAPED MOLARS IN A THICK-TAILED SHREW (SUNCUS MURINUS)

and the placenta deciduate. The testes are usually abdominal or inguinal but may be scrotal in a few species. Some insectivores produce one offspring at a birth, but most average at least five to a litter, and there may be two or more litters per year. Tenrecs are the most prolific, 16 or more being born at one time.

FIG. 2.—WELL-DEVELOPED CAECUM IN THE TREE SHREW DENDROGALE

Relationships.—Ancestral Menotyphla may well have given rise to the Primates (lemurs, monkeys, apes and man), Chiroptera (bats) and Dermoptera (flying lemurs or colugos). The oldest known insectivore lived in Asia during the Upper Cretaceous, roughly 70,000,000–80,000,000 years ago. The ancestry, descendants and even the interrelationship of these early insectivores cannot be satisfactorily determined from the fragmentary fossil evidence, but several primitive genera are known, all included in the family Deltatheridiidae. This group may have given rise to the North American branch of the insectivores, which appeared more than 10,000,000 years later, during the Lower Paleocene. One of the most interesting of early North American insectivores is *Palaeoryctes* of the Middle Paleocene. It was formerly regarded as ancestral to living zalambdodont insectivores and was placed at the base of the tenrec stock.

It now appears, however, that the classification of insectivores on the basis of the structure of the molars, whether V shaped or W shaped, is tenuous if not artificial. The cranial characters of *Palaeoryctes*, however, point to its menotyphlic affinities. Many other little-known Upper Cretaceous and Early Tertiary insectivores are included in the Menotyphla on purely negative evidence.

CLASSIFICATION AND SURVEY

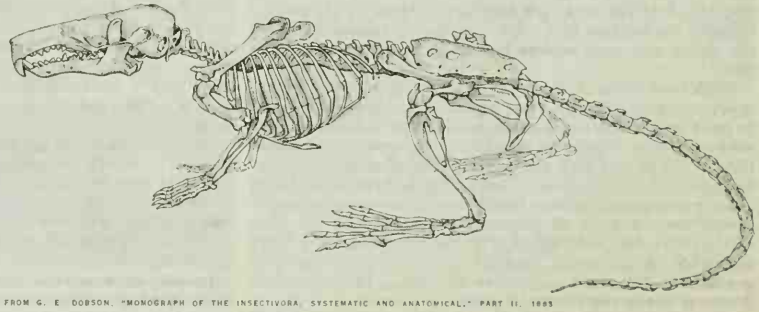
The following classification of insectivores includes the fossil (*) and living families.

Suborder Menotyphla
- Superfamily Deltatheridioidea
  - *Family Deltatheridiidae (Upper Cretaceous, Asia; Paleocene-Eocene, Nnrth America)
  - * " Palaeoryctidae (Paleocene, North America)
  - * " Leptictidae (Cretaceous-Oligocene, North America; Paleocene-Eocene, Europe)
  - * " Zalambdalestidae (Cretaceous, Asia)
  - * " Apternodontidae (Oligocene, North America)
  - Families of uncertain position:
    - *Nyctitheriidae (Paleocene-Eocene, North America; Eocene, Europe)
    - *Pantolestidae (Paleocene-Eocene, North America; Eocene, Europe)
    - *Mixodectidae (Paleocene-Eocene, North America)
    - *Aphelsicidae (Paleocene-Eocene, North America)
- Superfamily Tupaioidea
  - *Family Anagalidae (Oligocene, Asia)
  - " Tupaiidae, tree shrews (Recent, Asia)
- Superfamily Macroscelidoidea
  - Family Macroscelididae, jumping or elephant shrews (Recent, Africa)

Suborder Lipotyphla
- Superfamily Erinaceoidea
  - Family Erinaceidae, spiny and hairy hedgehogs (Eocene-Pliocene, North America; Eocene-Recent, Europe; Oligocene-Recent, Asia; Miocene-Recent, Africa; Recent, Philippines)
  - * " Dimylidae (Oligocene-Miocene, Europe)
  - " Talpidae, moles (Eocene-Recent, Europe; Oligocene-Recent, North America; Recent, Asia)
- Superfamily Soricoidea
  - Family Tenrecidae, tenrecs, potamogales (Recent, Africa, Madagascar)
  - " Chrysochloridae, golden moles (Miocene-Recent, Africa)
  - " Solenodontidae, solenodons, alamiquis (sub-Recent-Recent, Cuba, Isle of Pines, Hispaniola, La Gonave, Puerto Rico)
  - " Soricidae, true shrews (Oligocene-Recent, North America, Europe; Miocene-Recent, Africa; Pliocene-Recent, Asia; Recent, Madagascar, Philippines, Celebes, Moluccas, South America)

Only the living families are discussed in the following survey. Skull characters and dentition, important in identification, are emphasized.

Jumping Shrews (Macroscelididae).—African jumping shrews are the size of a mouse or rat, with the hind limbs considerably larger than the forelimbs and the tail long. The snout is well produced (hence the name "elephant shrew" for some genera), and the skull triangular in shape, with the brain case comparatively well expanded, postorbital processes little developed or absent, zygomatic arches never perforated, tympanic bullae well developed, the bony palate perforated (except in *Rhynchocyon*), and the mandible with the upper border of coronoid process and condyle on the same level. The female has three pairs of mammae but



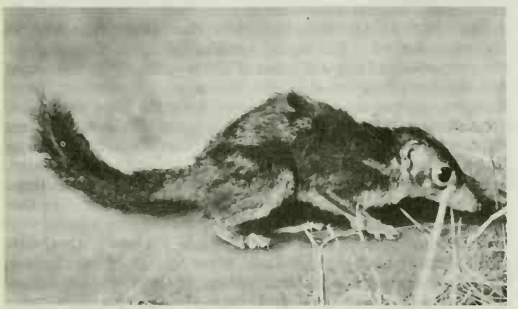
FROM G. E. DOBSON, "MONOGRAPH OF THE INSECTIVORA, SYSTEMATIC AND ANATOMICAL," PART II, 1883

FIG. 3.—SKELETON OF THE RUSSIAN DESMAN (DESMANA MOSCHATA)

produces only one or two young in a litter. Jumping shrews are diurnal as well as nocturnal and are common in arid or semiarid regions.

Typical jumping shrews, or elephant shrews, have five toes on each front foot, comparatively long nasal bones, short frontals. Postorbital processes are absent, and there are three upper incisors on each side of the jaw and small canines. The genus *Elephantulus* has a narrow snout, large ears, five toes on each hind foot and 40 teeth. The dengoli (*Nasilio*) has 42 teeth and a shorter snout; the common elephant shrew (*Macroscelides*), with the same dental formula, has a long snout and a pair of occipital protuberances formed by the greatly enlarged auditory bullae. *Petrodromus*, which has four toes on each hind foot, includes one species (*Petrodromus tetradactylus*) with the bristles on the underside of the tail being normal and not rough to the touch, and two others (*P. sultan* and *P. rovumae*) with the bristles terminating in rough knobs. *Rhynchocyon*, with a checkerboard pattern on its back, has four toes on each fore and hind foot, small postorbital processes, relatively short nasals and large frontals, one upper incisor and an elongated canine.

Tree Shrews (Tupaiidae).—The squirrellike tree shrews and the pen-tailed tree shrew are forest dwellers, diurnal and much more terrestrial than arboreal. They are characterized by a pointed snout with a naked tip, well-developed ears and a long tail, with at least the terminal half well covered with hair. The fore and hind limbs are approximately equal in length, and each has five toes with recurved claws. The skull is somewhat pear-shaped, with



ZOOLOGICAL SOCIETY OF LONDON

MALAY TREE SHREW (TUPAIA)

the rostrum well defined, orbits large and ringed with bone, zygomatic arches perforate, auditory bullae moderately developed, palate slightly fenestrated and coronoid process of mandible high. The dental formula is: I $\frac{2}{3}$, C $\frac{1}{1}$, P $\frac{3}{3}$, M $\frac{3}{3}$ = 38; the molar crowns are W shaped, upper incisors large and caniniform and the upper canine small and like the first premolar. A caecum is present, though sometimes small, and there is a permanent scrotum, a condition unique in insectivores. The cerebral hemispheres are extremely well developed, and the olfactory lobes are relatively smaller than in other insectivores.

True tree shrews are distinguished from pentails by the squirrellike tail, pointed snout and zygomatic arch with a large perforation. The genus of common tree shrews, *Tupaia*, has the lower canine larger than the adjacent incisor. The numerous species of *Tupaia* are distributed throughout the tropical forests of the Philippines and the Indo-Malaysian region. The genus *Anathana*, of India, resembles *Tupaia* externally but the zygomatic perforation is smaller and the lower canines are similar in size and appearance to the adjacent incisor. *Dendrogale*, of Indochina and Borneo, comprises the smallest of tree shrews, with the tail rounded and close-haired and the second incisor as large as the first. *Urogale*, of Mindanao in the Philippines, is similar but somewhat larger, and with the second incisor larger than the first and third.

The pen-tailed tree shrew, *Ptilocercus*, the typical genus of the subfamily Ptilocercinae, lives in Borneo, Sumatra and the Malayan peninsula. The basal two-thirds of the very long tail is naked, the terminal third being furnished with a featherlike brush of hair. (*See* TREE SHREW.)

Hedgehogs and Allies (Erinaceidae).—The hedgehog family is divided into the subfamily Erinaceinae, the true or spiny hedgehogs of Europe, Asia and Africa, and the subfamily Echinosoricinae, the hairy hedgehogs or gymnures, chiefly Indo-Malayan in distribution. The Erinaceinae are characterized by a dense covering of spines on the back, a vestigial tail and 36 teeth. The typical genus, *Erinaceus*, includes the common European and Asiatic hedgehog, *E. europaeus*. Its young are born blind and with soft spines that are soon replaced with rigid ones. The common hedgehog is a hibernator and is known to have a high immunity to poisons. Other species of *Erinaceus* (*E. algirus*, *E. frontalis*, *E. albiventris*) range from the western Mediterranean region southward into the northern half of Africa. *Hemiechinus* is a genus of Asiatic large-eared hedgehogs. *Paraechinus*, of north Africa and Asia, has peculiarly inflated pterygoid bones.

The Echinosoricinae are distinguished by a hairy, not spiny, coat, well-developed tail and 40 or 44 teeth. The typical genus, *Echinosorex*, of Borneo, Malaya, Indochina and Burma, is opossumlike with a long, coarse pelage, black and white or whitish; a long scaly tail, pale at the tip; and 44 teeth. *E. gymnurus* is the largest insectivore. *Hylomys*, of Java, Sumatra, Borneo and Yunnan, is volelike, with a soft coat and a very short hairy-tail, about one-fifth the length of the head and body combined. *Neotetracus*, of southern China and Tonkin, with a tail more than one-half the length of the head and body, has 10 teeth in each half jaw for a total of 40. The upper canine is larger than the adjacent incisor. *Podogymnura*, of the Philippines, is about the same size as *Neotetracus* but its tail is one-third the length of the head and body, and its upper canine is smaller than the adjacent incisor. (*See* HEDGEHOG.)

Moles (Talpidae).—Moles, with few exceptions, are well adapted for burrowing or swimming. They are common throughout the temperate zones of Europe and Asia. The common old-world mole, *Talpa europaea*, perhaps extends into the Arctic region in Siberia. Moles are small to moderate in size, with cylindrical bodies and fur. The tail and limbs are short; each foot has five toes adapted for burrowing or swimming except in the shrew mole (*Uropsilus*). The snout is conical and produced into a proboscis. The small eyes are sometimes covered by skin and the ears generally have auricles. The crowns of the molars are W shaped and upper and lower canines are present. The skull is flattened and narrow, with cranial bones fused at an early age, auditory bullae not well developed; the tympanic bone is joined to the cerebral capsule; zygomatic arches are present, though often weakly developed, and the postorbital processes are absent; the articular process of the mandible has two facets. The pectoral muscles are enormously developed in the burrowing forms. As a rule a female produces a single litter of one to six young during the year.

Moles are grouped in five subfamilies. Uropsilinae, with *Uropsilus*, is the most primitive. This genus is shrewlike in form without specializations for digging or swimming. It occurs in western China and northern Burma. Several other genera of shrew moles have been described on the basis of dental characters, but all appear to belong to a single, dentally variable species, *Uropsilus soricipes*. The usual number of teeth is 38.

The subfamily Desmaninae includes two kinds of aquatic moles with front feet normal, hind feet enlarged and webbed. One, *Galemys pyrenaicus*, the Pyrenean desman of France, Spain and Portugal, has a combined head and body length of five inches, the tail being somewhat longer and with the tip flattened from side to side. The other, the Russian desman (*Desmana moschata*), is about eight inches long, the tail being about as long and flattened throughout its length.

True moles of the subfamily Talpinae are all closely related species of the genus *Talpa*. The common mole (*Talpa europaea*) occurs throughout most of Europe, Siberia and Mongolia; the other species are found elsewhere in Asia. True moles are short-tailed, with the eyes generally covered by skin and the front feet extraordinarily expanded into shovellike digging tools. The dental formula is: I $\frac{3}{3}$, C $\frac{1}{0-1}$, P $\frac{3-4}{3-4}$, M $\frac{3}{3}$ = 40–44.

The subfamily Scalopinae comprises eight genera of extremely small Asiatic and North American burrowing moles with external ears absent, forefeet enlarged for digging and canine and first upper premolars very small. *Scaptonyx fusicaudus*, of western China and northern Burma, is about three and one-half inches long, its tail being more than half as long and well haired. *Scapanulus oweni*, of China, is four inches long, with an enlarged front upper incisor. *Urotrichus*, with two species confined to Japan, is slightly smaller. The American shrew mole (*Neurotrichus gibbsi*), of the northwestern United States, with a length of about three inches is the smallest of American moles. The three species of *Scapanus* are restricted to western United States and bordering parts of Canada and Mexico. They are four or more inches long, robust, with short naked tails and three lower incisors. *Scalopus*, of the eastern half of the United States, is similar but larger with thinly haired tail, webbing between the front toes, and two lower incisors. The hairy-tailed mole (*Parascalops breweri*) of northeastern United States and bordering parts of Canada is much smaller with a densely haired tail and laterally placed nostrils.

The subfamily Condylurinae contains only the unusual star-nosed mole (*Condylura cristata*) of northeastern United States and eastern Canada. This species is five to six inches long, the tail being more than one-third as long, and the tip of the snout is adorned with a characteristic ring of 22 fleshy appendages. (*See* Mole.)

Tenrecs and Potamogales (Tenrecidae).—The tenrecs and potamogales live in Madagascar and western Africa, respectively. The skull is elongate, lacks the malar and zygomatic arches, but has the tympanic bone ringlike, the auditory bullae variable in development, postorbital process absent and molars V shaped or W shaped. The penis is retractile and the testes abdominal. The subfamily Tenrecinae comprises the tenrecs. The common tenrec (*Tenrec* or *Centetes*) is a pale brown animal about the size of a small rabbit with long harsh or spiny hair and virtually no tail. The dental formula is: I $\frac{2}{3}$, C $\frac{1}{1}$, P $\frac{3}{3}$, M $\frac{3}{3}$ = 40. The female has 12 pairs of mammae and produces 16 or more young at a birth. Tenrecs spend the dry season hibernating in their burrows. *Setifer* is a hedgehoglike tenrec with 36 teeth. *Echinops* and *Dasogale* are similar but smaller and have 32 teeth each. The streaked tenrec (*Hemicentetes*), with 40 teeth, is less spiny and characterized by the broad black and white bands running the length of its body. The burrowing rice tenrec (*Oryzorictes*) is shrew- or molelike in appearance, with fine fur, short but well-developed tail, small eyes, small external ears and 40 teeth. *Microgale* and *Limnogale* are closely related ratlike tenrecs with long tails and aquatic habits. *Geogale* (including *Cryptogale*) is a shrewlike tenrec with large ears, 34 teeth and unknown habits.

The subfamily Potamogalinae comprises two genera of aquatic insectivores confined to western equatorial Africa. The otterlike *Potamogale* has a combined head and body length of about 12 in.; a thick, laterally flattened tail equally long; nostrils protected by valves; toes unwebbed, but the second and third hind toes united by skin for two-thirds their length; tympanic bullae well developed; and molars weakly W shaped. *Micropotamogale* is similar but smaller and shrewlike, with the tail cylindrical as in tenrecs, narial valves absent and molars more nearly V shaped. *Potamogale* depends entirely on the action of its tail for propulsion through water. The habits of *Micropotamogale* are little known. (*See* Tenrec.)

ZOOLOGICAL SOCIETY OF LONDON

TAILLESS TENREC (TENREC ECUADATUS)

Golden Moles (Chrysochloridae).—Golden moles are blind, burrowing insectivores ranging from the Cameroons to southern Africa. The small body, robust and nearly cylindrical in form, is carried on short legs and has a rudimentary tail. The pelage is silky with a metallic luster; the neck is short and thick and the muzzle bluntly conical, with the tip naked. The external ears are hidden in fur, and the eyes are small or covered with skin. Each forefoot has four toes, of which two or three are armed with large thick claws adapted for burrowing, and each hind foot has five toes. The skull is conical in outline, with sutures prematurely obliterated, postorbital constriction not defined, postorbital processes absent, zygomatic arches and auditory bullae well developed. The teeth number 36 to usually 40. (*See* Golden Mole.)

Solenodons (Solenodontidae).—The West Indian solenodons, or alamiquis, are large shrewlike insectivores with a combined head and body length of about ten inches and a nearly naked tail almost as long. The nostrils open to the side, the eyes are small and the external ears well developed. Scent glands are present in the axillary and inguinal regions. Solenodons have 40 teeth; the molar crowns are V shaped. One species, *Solenodon cubanus*, lives in Cuba; another, *Solenodon paradoxus*, in Haiti. A second genus, also from the Greater Antilles, is the smaller and recently extinct *Nesophontes*.

True Shrews (Soricidae).—More than 100 species of true shrews are known. The typical kinds are distributed throughout the temperate and tropical zones of Europe, Asia, North America and the temperate zone of the Andes of northwestern South America. Shrews are absent in Australia and the polar regions but are present in many oceanic islands, in some of which they were introduced by man. Shrews are small, the largest is no bigger than a common rat. The pelage is soft, the snout long and pointed, eyes small, external ears more or less developed and sometimes provided with valves for closing the auditory meatus. Five toes are present on each foot. The tail is variable in length but always well developed. The teeth number from 26 to 32; the molar crowns are W shaped; the single lower incisor of each side is strongly developed and forward projecting; the first upper incisor is large, with a well-developed cuspule on its posterior base; second and third incisors and anterior premolars are unicuspidate and undifferentiated from each other; canines are absent; and milk dentition evidently missing. The skull is long and narrow, with bones fused at an early age, zygomatic arches absent, tympanic bullae absent, tympanic bone ringlike and free, articular process of mandible with two articular facets.

All shrews are nocturnal and terrestrial. Some climb on occasion, a few are well adapted for aquatic life and one species is a burrower. The metabolic rate of shrews is extremely high, few being capable of surviving half a day without food. The saliva is highly toxic and aids the shrews in subduing and killing prey, which varies from slugs, worms, insects and spiders to mice and small birds. Most shrews produce three to ten young in a litter, the young being born blind and naked.

Shrews are arranged in three subfamilies: Soricinae, with the tips of the teeth red or brown; Crocidurinae, with white teeth; and Scutisoricinae, with a peculiar vertebral column unlike that of any other mammal.

The genus of common shrews, *Sorex*, typical of the subfamily Soricinae, contains about 38 species in North America and 9 species in Europe and Asia. It is the only insectivore genus common to both hemispheres. Species of *Sorex* have small, slender bodies, ranging in colour from brown to black. The tail is less than one-half the combined head and body length, hairy in young individuals and naked in the old. The snout has well-developed vibrissae; the eyes are minute; three pairs of inguinal mammae are present in the female. The dental formula is: I $\frac{3}{1}$, P $\frac{4}{2}$, M $\frac{3}{3}$ = 32. The American pygmy shrew (*Microsorex*), represented by a single species (*M.*

hoyi), measures less than two inches in combined head and body length; it is the smallest American shrew. The largest American shrews are the short-tailed shrews of the genus *Blarina*, with one, possibly two, species; they average about three and one-half inches in head and body length. Their dental formula, as well as that of *Microsorex*, is the same as in *Sorex*. *Cryptolis*, another genus of small American shrews, comprises about 28 species, of which one lives in the high Andes of Venezuela, Colombia and Ecuador, the others in Central America, Mexico and the eastern part of the U.S. The dental formula of *Cryptotis* is: $I\frac{3}{1}$, $P\frac{3}{3}$, $M\frac{3}{3} = 30$. The remaining North American genus, *Notiosorex*, has the dental formula $I\frac{3}{2}$, $P\frac{2}{1}$, $M\frac{3}{3} = 28$. The Asiatic *Soriculus*, with six species, resembles *Sorex* but is larger and has only 30 teeth. *Chodsigoa*, with three species, also Asiatic, is very similar but has 28 teeth. *Blarinella*, with a single species in western China and northern Burma, is also like *Sorex* but has a shorter tail, smaller ears and somewhat specialized claws. *Neomys*, of Asia, comprises two species of aquatic shrews with broad fringed hind feet and tails with a keel of stiff hairs.

All white-toothed shrews (Crocidurinae) are native to the old world. The typical genus, *Crocidura*, comprises about 20 species (though more than 200 have been described). Crociduras are characterized by the long bristles of the tail. The dental formula is: $I\frac{3}{1}$, $P\frac{2}{2}$, $M\frac{3}{3} = 28$. Species occur in Europe, Africa, Asia, Indonesia and the Philippines. The thick-tailed shrews of the genus *Suncus* are native to the warm parts of Europe, Africa, Asia, Indonesia and the Philippines. There are ten species. The largest, *S. murinus*, about the size of a house rat, has been introduced by man into many parts of the world. The smallest species, *S. etruscus*, with the head and body length less than two inches, is perhaps the smallest mammal in the world; it occurs throughout most of the range of the genus. The tail of *Suncus* is characterized by long bristles, as in *Crocidura*. The dental formula is: $I\frac{3}{1}$, $P\frac{3}{2}$, $M\frac{3}{3} = 30$. *Myosorex*, with three African species called "mouse" shrews, is similar to *Suncus* but lacks caudal bristles and has three premolars in both upper and lower jaws. *Surdisorex*, another African genus, with two species, is densely furred, with ears greatly reduced and claws well developed. The dental formula is: $I\frac{3}{1}$, $P\frac{2-2}{2-3}$, $M\frac{3}{3} = 28$ or 30. *Solisorex*, of Ceylon, is a burrower; it has enlarged claws on each forefoot, a tail without bristles, simple lower incisors and 28 teeth. *Feroculus*, another Ceylonese burrower, has the digging claws of each forefoot even larger, the tail with bristles, the cutting edge of lower incisor lobed, and 30 teeth. *Anourosorex*, with two species in southeastern China, Tibet and northern Burma, is also adapted to underground life. The tail and ears are vestigial. The dental formula is: $I\frac{2}{1}$, $P\frac{2}{2}$, $M\frac{3}{3} = 26$. The aquatic *Nectogale*, with one species in Tibet, has the long, thick tail fringed above and below; external ears absent; hind feet fringed; toes fully webbed; and soles with adhesive pads for clinging to slippery rocks in mountain streams. The less specialized *Chimarrogale*, with one species ranging from the Himalayas to Japan and another in Borneo and Sumatra, has external ears, toes not webbed and tail fringed below only. *Nectogale* and *Chimarrogale* eat arthropods, including crustaceans, and small fish. *Diplomesodon* of eastern Russia is piebald, with the tail covered with white hair and tufted at the tip.

The subfamily Scutisoricinae, with a single genus and species, is known only from the upper Congo river basin in Africa. The genus *Scutisorex*, the armored shrew, measures nearly five inches in length, the tail somewhat less. The fur is long and thick and the skull is heavily ridged, with the brain case strongly roughened. The spinal column has almost twice the number of vertebrae found in other insectivores. The transverse processes of each vertebra are hypertrophied and interlocked with the adjacent processes in a manner which gives the spine the appearance of a long narrow canoe. This odd-shaped structure can resist the pressure exerted by a man standing on it and the stomp of any ungulate traveling over the littered forest floor where *Scutisorex* lives. (*See* SHREW.)

INSECTIVOROUS PLANTS: *see* CARNIVOROUS PLANTS.

INSEIN, a town and district in the Pegu division of the Union of Burma, lies immediately north of Rangoon. Area of district 1,903 sq.mi.; pop. (1962 est.) 537,291. The district includes a large tract of the Irrawaddy delta on either side of the Hlaing or Rangoon river and on the east of the Irrawaddy itself. In the east of the district is a portion of the southern end of the Pegu Yomas clothed with dense evergreen forest which, in spite of its nearness to Rangoon, was still the haunt of wild elephants in modern times. The Rangoon-Prome line of the Burma railways runs through the district.

INSEIN, the chief town, lies 10 mi. N.W. of Rangoon, of which it has become almost a suburb, especially since the independence of Burma in 1948 and the subsequent rapid growth of Rangoon. The town has railway workshops, a government engineering school and veterinary college, and a large jail. (L. D. S.)

INSELBERG. An isolated hill standing above well-developed plains, in appearance not unlike an island above the sea (hence the name). Although the term is sometimes applied generally, most geologists restrict its use to such hills formed under tropical and subtropical conditions, as in Nigeria (*q.v.*), usually formed of plutonic rocks such as granite and gneiss, and characterized by steep curved sides of smooth bare rock. These bare rock domes, which may stand 1,500 ft. above the plains, are more specifically called bornhardts and display an onionlike "peeling" (exfoliation) of concentric rock shells, in thickness from a few inches to 20 ft., from the surface. A pediment, or low-angle slope slightly concave upward, is usually present at the base of the inselberg. In its later stages an inselberg may develop into a *kopje; i.e.*, a residual hill composed of a pile of large boulders, in form similar to the granite tors of Devon and Cornwall. Isolated hills similar to inselbergs but formed under nontropical conditions are known as monadnocks. (J. C. PH.)

INSHTATHEAMBA (BRIGHT EYES) (1854–1903), American Indian writer and lecturer who promoted public interest in reform of the U.S. government's Indian policies, was born in Nebraska on the Omaha reservation. She was the daughter of a former Omaha chief, Inshtamaza or Iron Eye. His father, Joseph La Flesche, who married an Omaha woman, was a French trader, and Iron Eye also bore his father's name. Bright Eyes was originally named Susette La Flesche but later adopted her Indian name. She studied at a mission school on the reservation and later was educated at a private school in Elizabeth, N.J. She thereafter was a teacher in a government school on the reservation.

Bright Eyes won wide public interest in 1879 as an outspoken advocate of Indian rights. In that year she toured the eastern states to call attention to the government's arbitrary action against the Ponca tribe. In 1877 the Poncas, related to the Omahas, had been forced to leave their reservation on the Niobrara river in South Dakota and to emigrate to the southern Indian territory. The tribe found living conditions there intolerable, however, and led by chief Standing Bear traveled north on foot for about 600 mi., arriving at the Omaha reservation in March 1879. The Indians were arrested and ordered to be returned to their new home. On April 30, 1879, the federal district court held, however, that they should be freed under a writ of habeas corpus.

Bright Eyes, noted for her eloquence as a speaker, edited *Ploughed Under, the Story of an Indian Chief* (1881). She died on the Omaha reservation, near Bancroft, May 26, 1903.

INSIDE PASSAGE or INLAND PASSAGE is a sheltered sea route extending from Seattle, Wash., approximately 1,000 mi. to Skagway, Alaska. Protection from winds and storms is provided

by Vancouver Island, by a series of islands lying eastward of Hecate strait and, in Alaska, by the Alexander archipelago. Vacationers have favoured this waterway, both for its great natural beauty and its customary smoothness.

The greatest width of the chain of islands is about 80 mi. Their rugged topography is concealed beneath heavy forests and dense undergrowth. Several small glaciers may be seen from the channel. Rainfall is heavy, and may be expected at any season.

Navigation.—The shores of the channel drop off sharply, and in most places there is ample depth for all vessels. Anchorages are numerous. Tidal currents attain considerable velocity in places. Extensive surveys have practically eliminated unmarked pinnacle rocks which have caused several notable marine disasters. Pilotage is not required, but is desirable.

Principal towns along the passage include Victoria, Vancouver and Prince Rupert in British Columbia and Ketchikan, Wrangell, Petersburg, Juneau and Skagway in Alaska. (J. E. Cl.)

INSIGNIA, MILITARY. Ever since men first organized themselves into large groups for fighting they have employed certain signs or insignia to indicate their rank, branch of service and special duties or qualifications. Except for commanders of high rank, insignia were usually rather simple in ancient and medieval forces, but since the 18th century insignia for all ranks have developed along rather complicated and rigid lines. Many different devices have been used, including cockades, epaulets, hat cords, ribbons, buttons, badges, ornaments, bars, clasps, chevrons, stripes, braids and shoulder patches. In some instances there has been an evolvement of these devices. An example of this process of evolution is the epaulet (*q.v.*) which once was a major means of indicating both rank and function. Remnants of the epaulet today are the shoulder board and the shoulder strap to which are attached insignia of rank.

Although the following article deals primarily with various insignia devices which are attached to the uniform it must be remembered that the uniform is itself a form of insignia, indicating by its colour and cut the particular branch of service to which its wearer belongs. In a general way it may also indicate the rank of the wearer, particularly whether he is an officer or an enlisted man. (*See* Uniforms.)

Insignia, particularly the flags, of military organizations are discussed in the article Colours, Military.

UNITED STATES

In spite of many interesting stories about origins, the early development of rank insignia in the United States was a haphazard affair. At the start of the American Revolution it was difficult to distinguish between officers and enlisted men of the Continental army. Some "badges of distinction" were deemed necessary. Gen. George Washington wore "a light blue ribband across his breast between his coat and waistcoat." A brigadier general was assigned a pink ribbon; a major general a purple ribbon; and aides, green. Field officers were distinguished by hat cockades, red or pink. Captains wore yellow or buff cockades while lieutenants wore green. An epaulet on the shoulder with a silver star to denote the rank of general came into use near the end of the war. The colonel's eagle did not appear until about 50 years later.

Army.—The insignia of the arms and services of the U.S. army in the 20th century have followed a fairly consistent pattern and have borne an understandable relationship to the functions of the arm or service to which they apply. The crossed flags and torch of the signal corps and the flaming bomb of the ordnance corps are examples. (*See* fig. 2.) The latter is said to be the oldest of U.S. insignia, having been adopted in 1832. Originally the flaming bomb represented both artillery and ordnance and was embroidered in gold on officers' long-skirted coats. In addition to such devices, each branch of the army has its own distinctive colour; for example, infantry, light blue; armour, yellow; artillery, scarlet.

Insignia of grade are normally worn on shoulder loops by commissioned and warrant officers. (*See* fig. 1.) Noncommissioned officers wear gold-coloured chevrons (point up) on both sleeves. Enlisted specialists wear an eagle device with varying numbers of arcs above on both sleeves. On some uniforms, commissioned officers wear rank insignia on their right shirt collar and on their garrison caps; enlisted men wear unit insignia or regimental crest on the garrison cap. All personnel wear grade insignia on combat helmets. Combat leaders wear a green cloth loop around the middle of both shoulder loops of the outer garment. Branch insignia are worn on the left collar or, by officers, on both coat lapels.

In 1959 and again in 1965 the insignia worn by enlisted men and women in the U.S. army were changed. The result was the authorization in 1965 of ten distinct titles, each with its own insignia, ranging from private first class to sergeant major, plus four specialist ratings. Included was a new grade, lance corporal, placed between private first class and corporal. At the same time the two top grades (both in the same pay bracket, E-9) became sergeant major and chief master sergeant. The next two grades (both in the same pay bracket, E-8) were first sergeant and master sergeant. Two specialist grades (8 and 9) were eliminated.

Members of colour-bearing units such as regiments, separate battalions and service schools wear small enameled shields bearing the regimental, unit or school coat of arms in the middle of both shoulder loops on the outer garment. Members of major commands, armies, corps, divisions and independent commands often wear distinctive shoulder patches on the upper part of the left sleeve of their outer uniform. Many of these patches were designed for units serving in World Wars I and II and the Korean War. Both officers and enlisted men may wear the shoulder patch of the overseas unit they served with during World War II or the Korean War. This is worn at the top of the right sleeve of the uniform.

Officers on duty with the general staff of the department of the army in Washington, D.C., wear a green, black and gold medallion (general staff identification badge) on the right breast pocket. After one year's service on the army general staff, the officer is permitted to wear this insignia permanently. A similar device, the department of defense identification badge, is awarded to U.S. armed forces personnel who serve on the staff of the department of defense and is worn on the left breast pocket.

The letters "U.S." in a circle are worn by all army and air force enlisted personnel on the right coat collar and on both collars by basic trainees. Officers wear the "U.S.," without background, on both coat collars when branch insignia are worn on the lapels. On certain working uniforms the words "U.S. Army" in gold on a black background are worn on the upper left breast.

Air Force.—Insignia of rank for officers of the air force are the same as the army's except for warrant officers whose bars have sky blue rather than brown stripes. (*See* fig. 1.)

Enlisted ranks are designated by silver-coloured chevrons on a dark blue background, rounded point downward, and a silver-coloured star with a centre of dark blue.

As in the other services, air force aides and attachés are distinguished by aiguillettes. These are worn on the left shoulder except for presidential aides who wear them on the right. Aides are further identified by collar insignia designating the office or commander to whom they are assigned. Air force aviation badges are spread wings of silver colour bearing identifying centre designs and worn above the left breast pocket.

Marine Corps.—Marine officer insignia are similar to those for the army except that warrant officers' bars are broken by scarlet, rather than brown, stripes. (*See* fig. 1.) Officers wear their rank on both shirt collars and on shoulder loops of coats. Naval medical officers, chaplains and others serving with fleet marine forces and wearing marine uniforms wear their rank device on the right shirt collar and their staff corps device on the left. A bursting bomb device worn by certain warrant officers who were designated marine gunners was declared obsolete in 1965. Enlisted men wear cloth chevrons of rank on both sleeves of most uniforms and metal chevrons on the collars of certain working uniforms. All officers and all enlisted men of the rank of corporal or above wear a scarlet stripe along the outer seam of each trouser leg with the blue uniform. The marine corps emblem is worn on most headgear, coats and jackets. Rank insignia are also worn on

garrison (fore-and-aft) caps. Shoulder patches, worn by marines during World War II, are no longer authorized. There are no branch insignia.

Navy.—Commissioned and warrant officers of the navy wear stripes indicating rank on coat sleeves or shoulder boards, the colour of the stripes depending on the colour of the uniform. (*See* fig. 1.) Devices above the stripes distinguish between line and staff corps officers. Flag officers also wear on their shoulder boards a foul anchor and one or more stars according to rank (five stars in a circle for a fleet admiral). Rank may also be designated by metal insignia of the army type except that warrant officers wear single bars broken by blue instead of brown. Such insignia are worn on both shoulder loops of the raincoat and on both shirt collars by line officers. Staff corps officers and warrant officers wear the rank device on the right shirt collar and the staff corps or specialty insignia on the left. As in the other services, higher ranks (commander and above) are distinguished by braid ornamentation on cap visors.

Navy enlisted personnel of the three lowest pay grades are designated by diagonal stripes worn on the left sleeve. Petty officers wear chevrons (point down) surmounted by an eagle and, in the case of the top two pay grades, by one or two stars. Between the chevrons and the eagle is a device indicating the petty officer's specialty. The device, as a whole, is known as a rating badge. Until after World War II seven specialty ratings (signalman, boatswain's mate–coxswain, fire controlman, gunner's mate, torpedoman, quartermaster and turret captain) were worn on the right sleeve, all others on the left. Thereafter, all rating badges were worn on the left sleeve. Depending on the uniform, enlisted rank insignia are of silver, blue, white, khaki, silver-khaki or green. Petty officers with 12 years' good conduct may wear gold rating badges.

Naval aviation badges for navy, marine corps and coast guard personnel are spread wings of gold colour worn above the left breast pocket. Submarine, parachutist and aircrew badges are worn in the same manner. The name of his ship, aircraft squadron or other special unit may be worn by an enlisted man below the rank of chief petty officer. Before World War II these unit identifying marks were worn on the hatband of the winter "flat" hat. During the war they were ordered removed and the words "U.S. Navy" substituted. In the mid-1950s identifying marks were again authorized, but were to be worn on the right sleeve just below the shoulder seam.

Coast Guard.—Coast guard officers and enlisted men wear insignia identical to those of the navy except for the officers' and chief petty officers' cap devices and the shield worn by officers in place of the navy's line or staff corps devices. Enlisted men wear the shield on the right sleeve, just above the cuff.

Service Stripes.—Enlisted men of all services wear diagonal service stripes denoting length of active service on the lower part of the left sleeve. The World War I overseas and wound chevrons and the World War II and Korean War horizontal overseas bars may be worn on the left sleeve by personnel of the army and air force.

BRITISH COMMONWEALTH

Great Britain.—*Army.*—Insignia of rank are worn by commissioned officers on epaulets and by warrant officers and noncommissioned officers on sleeves. Commissioned rank is distinguished by diamond-shaped stars ("pips") up to captain, a crown for a major and a combination of crown and stars up to a brigadier; general-rank officers wear a badge consisting of baton and sword crossed with either a star or crown, or with both star and crown for full generals. Field marshals of the British army wear crossed batons in a wreath with a crown above. Officers of the rank of colonel and above are distinguished by red bands around their caps. (*See* fig. 3.)

Warrant officers (referred to as sergeant majors) wear on their lower sleeves a badge incorporating the royal coat of arms (class I) or a crown within a laurel wreath or a crown alone (class II). Noncommissioned officers wear chevrons, point downward, on both upper sleeves: three chevrons surmounted by a crown for a quartermaster sergeant, three chevrons for a sergeant, two chevrons for a corporal and one chevron for a lance corporal. The different corps, regiments and brigades of infantry wear distinguishing badges and buttons.

Royal Navy.—Badges of rank are mainly worn on the sleeve. With blue uniform, officer rank is shown by rings of gold lace on the cuff incorporating a curl in the uppermost ring. A sublieutenant wears one ring, a captain four rings, a commodore one broad ring and an admiral of the fleet one broad and four ordinary rings. In white uniform, equivalent stripes are worn on the shoulder straps. Midshipmen wear white patches on the lapel; cadets a length of white twist. (*See* fig. 3.)

Badges indicating rating, *e.g.*, petty officer or leading seaman, are worn on the left arm and below them the good conduct badges. The various branches, gunnery, artisan, etc., are shown on the right arm, except in the case of chief petty officers, where they appear on the lapel, accompanied by three gilt buttons on the cuff. Ratings wear red badges on blue uniforms except with ceremonial uniforms which have gold badges; and blue badges on white uniforms.

Royal Air Force.—Except in the case of home and tropical mess dresses, R.A.F. officers wear rings of pale blue ranking lace bordered with black on all home and tropical uniforms. (*See* fig. 3.) A pilot officer wears one narrow ring, a flying officer one ordinary ring, a group captain four rings, an air commodore a broad ring and a marshal of the R.A.F. one broad and four ordinary rings. With home and tropical mess dresses, all officers wear gilt ranking lace.

On greatcoats, raincoats, working dress, all tropical uniforms, and flying overalls, ranking badges are worn on shoulder straps; on all other dresses, the ranking badges are worn on the sleeves. With ceremonial home dress, officers of the rank of air vice-marshal and above also wear distinctive shoulder straps.

Master aircrew and warrant officers wear rank badges on the lower sleeve in all uniforms; master aircrew wear an eagle within laurel wreaths surmounted by the royal arms and warrant officers wear the royal arms. Other airmen wear rank badges on the sleeves above the elbow; corporals and sergeants wear two and three chevrons respectively. Airmen aircrew also wear a gilt eagle above the rank badge. Flying badges are worn on the left breast above the pocket. Officers and airmen of certain specified branches wear distinguishing collar badges.

FIG. 3.—RANK INSIGNIA OF THE BRITISH ARMED FORCES

FIG. 4.—EXAMPLES OF INSIGNIA IN BRITISH COMMONWEALTH COUNTRIES: (A) OFFICER'S CAP BADGE FOR AUSTRALIAN AIR FORCE; (B) CANADIAN ARMY SHOULDER FLASH WITH SLEEVE BADGE OF WARRANT OFFICER CLASS 1

Canada.—*Army.*—Ranks and insignia for commissioned officers are the same as those of the British army. For noncommissioned officers, the Canadian coat of arms is incorporated in the sleeve badge of the warrant officer first class, while the warrant officer second class wears a wreath partially encircling a crown.

Navy.—Rank insignia are the same as that of the R.N., but unlike the R.N. the rank of commodore (one broad ring) is a full rank in the R.C.N. and promotion goes from captain to commodore to rear admiral. Among noncommissioned ranks the R.C.N. has no warrant officers and divides its chief petty officers into first class, wearing a crown over three sleeve buttons, and second class, wearing no crown. Petty officers are also divided, the first class wearing the "round rig" with crossed anchors surmounted by a crown on the sleeve, the second class wearing the sailor's or "square rig" with anchors but no crown. The R.C.N. makes no distinction in rank insignia for technical skill.

Air Force.—Commissioned ranks and insignia follow the R.A.F. However the R.C.A.F. divides warrant officers into first class, wearing on the sleeve the Canadian coat of arms, and second class wearing a crown and half wreath. The R.C.A.F. has no senior aircraftman but has a leading aircraftman below corporal, wearing a horizontal two-bladed propeller. Flight engineers wear a wing somewhat similar to that of pilots, navigators, etc., on the chest.

Australia.—Insignia in the Australian army and navy follow the British pattern. Insignia in the Australian air force follow the British pattern except that in mess dress miniature gold braid is worn on the shoulder straps.

New Zealand.—*Army.*—Insignia of rank follow the British pattern. New Zealand has, however, no distinguishing badges or buttons for brigades of infantry. The different corps and regiments wear distinguishing badges, buttons and shoulder flashes. Corps shoulder flashes worn by officers up to the rank of full colonel embody the words "New Zealand" in their title. Officers of colonel's rank and above do not wear corps shoulder flashes but wear "New Zealand" shoulder flashes when overseas.

Navy.—Rank insignia in the R.N.Z.N. follow the British navy. "New Zealand" shoulder flashes are worn by all ratings when serving with U.N. forces and when overseas, except when on loan or exchange services with other commonwealth navies.

Air Force.—Insignia of the air force follow the British model. Personnel serving overseas can be identified by "New Zealand" shoulder flashes.

India.—*Army.*—Rank insignia follow the British pattern, the crown on the shoulder strap of a general, lieutenant-general, brigadier, colonel, lieutenant-colonel and major being replaced by the three lions of Asoka. The Indian army, however, includes three ranks of junior commissioned officers above the NCO; on the shoulder strap a subedar-major wears the three lions of Asoka above a narrow stripe of gold lace bordered in red, the subedar wears two pips with a red and gold stripe and the jemadar one pip and a red and gold stripe.

Navy.—Gold ranking lace on the sleeves of commissioned officers follows the British pattern. All other badges of rank are identical to those of the R.N. with the exception of the crown which is replaced by the three lions of Asoka.

Air Force.—Ranking lace on the sleeves of commissioned officers follows the R.A.F. pattern except that the pale blue rings are bordered with navy rather than black. The highest rank is the air marshal with one broad and two other rings.

Pakistan.—*Army.*—Insignia of rank on winter dress, summer khaki and mess dress is similar to the British pattern, the *hilal* (crescent) in all cases having replaced the crown and the Mogul sword in the crossed swords and baton having replaced the crusader's sword. In addition there are three ranks of junior commissioned officers above the NCO: on the shoulder strap the subedar-major wears the *hilal* above a scarlet, Pakistan green, scarlet stripe; the subedar wears two *sitaras* (stars) above a scarlet, Pakistan green, scarlet stripe; the jemadar wears one *sitara* above a scarlet and green stripe. In the cavalry/armoured corps the subedar and subedar-major are known as risaldar and risaldar-major, with the same insignia.

Warrant officers, first class, wear on the lower sleeve a coat of arms in wreath with the Pakistan motto "Faith, unity and discipline." Distinguishing badges and buttons are worn by different regiments.

Navy.—Rank insignia in blue home dress is similar to the British pattern. In white summer uniforms, however, shoulder straps are worn as follows: a rear-admiral the crescent above the crossed Mogul sword and baton above one *sitara*, a vice-admiral with two *sitaras* worn vertically, an admiral with three *sitaras* and an admiral-of-the-fleet a crescent above crossed batons within a wreath. Officers from sublieutenant to captain wear equivalent stripes on the shoulder strap. Officers of certain specified branches wear distinction cloths between ranking lace on the sleeves in blue uniform.

Air Force.—In gray/blue winter dress and mess dress, rank insignia is similar to the British pattern; in summer khaki dress and mess dress equivalent stripes are worn on shoulder straps, the crescent replacing the crown on cap badges. All pilots and navigators are commissioned officers, wearing flying wings on the left breast with the initials PAF surmounted by the *hilal*. (X.)

OTHER COUNTRIES

Federal Republic of Germany (West Germany).—*Army* (*Heer*).—General officers of the army wear gray shoulder loops edged in gold except at the outer end. Gold diamond-shaped "stars" indicate rank; a gold wreath encircles the star at the outer end of the shoulder loop for all general officers. A general wears four stars; lieutenant general, three stars; major general, two stars; and brigadier general, one star. Field grade officers have gray, silver-edged shoulder loops ornamented with silver stars and a silver wreath at the outer end of the shoulder loop: colonel, three stars; lieutenant colonel, two stars; major, one star. The silver wreath is omitted for company grades: captain, three stars; first lieutenant, two stars; second lieutenant, one star. (*See* fig. 5.)

Warrant officers, master sergeant, and sergeant first class wear gold chevron type insignia on gray shoulder loops. Warrant officer I, one gold chevron with diamond; warrant officer II, two chevrons with diamond; chief warrant officer III, three chevrons with diamond. Master sergeant, two gold chevrons; sergeant first class, one gold chevron. The following enlisted men wear their gold rank insignia on the upper sleeves: sergeant senior grade, two chevrons; sergeant, one chevron; corporal technician, three oblique stripes; corporal, two oblique stripes; private first class, one oblique stripe; recruit, no rank insignia.

All commissioned and noncommissioned ranks wear coloured collar tabs to designate branch of service. General officers wear red collar tabs and general staff officers wear reddish-purple tabs.

Navy (*Marine*).—Commissioned rank is shown by gold stripes on sleeve cuffs and on shoulder boards. An admiral wears one board and three medium stripes; a commodore, one narrow and one wide stripe; a captain, four medium stripes; other ranks have lesser numbers of stripes.

The following ranks wear gold chevrons on both sleeve cuffs: chief warrant officer III, three chevrons with diamond at their

peak; chief warrant officer II, two chevrons and diamond; warrant officer I, one diamond and chevron; chief petty officer senior, two chevrons; chief petty officer junior, one chevron. The next lower ranks wear their gold insignia on both sleeves between the elbow and shoulder: petty officer, 1st class, two chevrons; petty officer, 2d class, one chevron; petty officer, 3d class, three oblique marks; seaman, two oblique marks; seaman apprentice, one oblique mark; seaman recruit is without insignia or rank. (*See* fig. 5.)

Air Force (*Luftwaffe*).—Insignia are identical with those of the army except that the collar tabs are yellow for ranks other than general officer.

German Democratic Republic (East Germany).—In uniforms and insignia the armed forces of East Germany retain most of the characteristics common to the German military forces of World War II.

Army.—Officers' rank is shown on the shoulder loops. An army general wears a plaited knot made up of five loops of sets of three cords, outer cords gold, central one silver, with four five-sided silver ornaments, arbitrarily called stars. A colonel general wears three stars, a lieutenant general two stars, and a major general one star. Shoulder loops for all general officers are superimposed on a red background while those of field grade officers are superimposed on a solid background coloured to indicate the branch of service. A colonel wears a knot made of four silver cords and designed in six loops, with three square-shaped pips of gilt; a lieutenant colonel wears two pips and a major wears one pip. A captain wears a shoulder loop covered with eight parallel rows of silver cord, the colour of the outside piping indicating arm or service; superimposed on the cord are four pips. A senior lieutenant wears the same shoulder loop with three pips; a lieutenant wears two pips and a junior lieutenant one pip.

Noncommissioned officers of the first three grades wear plain shoulder loops with two parallel rows of piping, the outer row

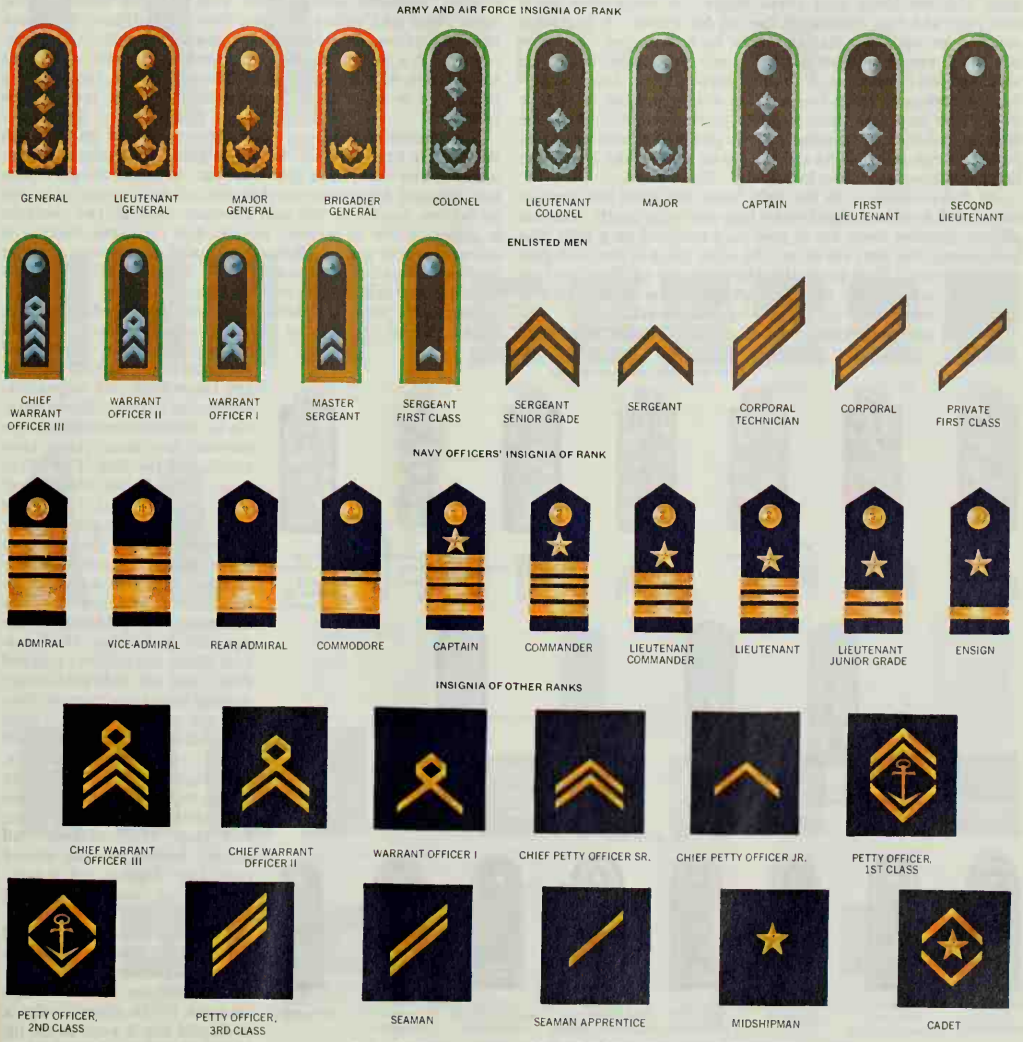

FIG. 5.—MILITARY INSIGNIA OF THE WEST GERMAN ARMED FORCES

coloured to indicate branch of arm or service. A sergeant major wears three silver pips and a junior sergeant wears no pips. Other enlisted ranks have shoulder loops ornamented with a single strip of piping coloured to show branch or service. A senior lance corporal wears two white cross stripes at the end of the shoulder loop; a lance corporal wears one white stripe; and a private wears a plain shoulder loop. (*See* fig. 6.)

Navy.—Commissioned rank is designated by sleeve braid and, for lieutenant commander and above, by gold shoulder boards similar to those of the army, but mounted on turquoise-blue background. An admiral wears three silver stars on gold shoulder board cord; on his sleeve, one broad stripe and three medium gold stripes. A vice-admiral wears two stars on his shoulder board and one broad and two medium gold stripes on his sleeve. A rear admiral wears one star on the shoulder board and one broad and one medium gold sleeve stripe.

A captain wears a silver cord shoulder board with three gold stars and one broad gold sleeve stripe. A commander wears two stars and four medium stripes on his sleeve. A lieutenant commander wears one star and three medium stripes. A senior lieutenant wears two medium stripes and one narrow stripe; his shoulder loop is the same as an army captain's, but with blue piping. A lieutenant wears two medium stripes and the same type of shoulder loop with three pips. A junior lieutenant wears one medium and one narrow stripe and two pips. An ensign wears one medium stripe on his sleeve and one pip on his shoulder loop. The lower ranks wear shoulder loops only. (*See* fig. 6.)

Air Force.—Insignia in the main follow the army but commissioned rank is on both the shoulder loop and collar patch. General officers' shoulder loops are of gold cord mounted on a light blue background; the stars are silver; the collar patch is blue with gold ornamentation. Field grade shoulder loops are of silver cord on light-blue background; the stars are gold; the collar patch is light blue ornamented by silver wing and wreath.

Enlisted men wear plain, light-blue collar patches with white wing centred, and shoulder loops similar to those of the army but of blue piping.

France.—*Army.*—Commissioned officers up to brigadier general wear rank insignia on the kepi, the beret and shoulder loops; marshals and generals wear stars indicating grade on sleeve cuffs instead of on shoulder loops. General officers wear a khaki field kepi bearing stars; dress kepi is ornamented with gold oak leaves. Silver stars indicating ranks of combatant arms and gold stars denoting ranks in the services are superimposed on black shoulder loops: marshal of France, seven stars on sleeve cuff and three rows of gold oak leaves on kepi; general of the army, five stars; lieutenant general, four stars; major general, three stars; brigadier general, two stars. Officers of the rank of colonel and below wear a kepi with gold, silver or gold and silver stripes around the top to indicate rank; the cap is coloured to indicate branch of service; shoulder loops have similar stripes superimposed on them, the stripes coloured according to arm or service: colonel, five gold stripes; lieutenant colonel, three gold and two silver stripes; major, four gold stripes; captain, three gold stripes; lieutenant, two gold stripes, second lieutenant, one gold stripe. Chief warrant officer, a gold stripe with a red thread. Warrant officer, one silver stripe with a red thread. Warrant officer kepis have a single gold or silver band around which a narrow red stripe is twisted.

Noncommissioned officers wear chevrons (point up) on both sleeves; the kepi is plain. Master sergeant, four gold chevrons; sergeant, first class, three gold chevrons; sergeant, one gold chevron; corporal, first class, two chevrons in colour of arm or service on bottom, topped by one gold chevron; corporal, two chevrons in colour of arm or service; private, first class, one chevron in colour of arm or service. Noncommissioned officers wear a similar number of bars on their garrison caps. Officer candidates wear a broken gold stripe on their shoulder loops. (*See* fig. 7.)

Navy.—No shoulder boards are worn, but an officer's badge (small gold tab) is worn on the tip of each shoulder. Flag officer cap bands are ornamented with gold braid; caps of captains and below bear gold stripes corresponding to rank. Sleeve insignia for commissioned officers are: admiral, five silver stars; vice-admiral of the fleet, four silver stars; vice-admiral, three silver stars; rear admiral, two silver stars; captain, five gold stripes; commander, three gold and two silver stripes; lieutenant commander, four gold stripes; lieutenant, three gold stripes; junior lieutenant, two gold stripes; ensign, one gold stripe; chief warrant officer, two narrow (gold and silver) and one wide gold stripe; warrant officer, one narrow silver and one wide gold stripe; chief petty officer, three diagonal gold stripes; petty officer, first class, two diagonal gold stripes; petty officer, second class, one diagonal gold stripe. Leading seaman, first class, three diagonal red stripes; leading seaman, second class, two diagonal red stripes; able seaman, one diagonal red stripe. (*See* fig. 7.)

Air Force.—Commissioned rank is designated by gold stars or gold and silver stripes on the sleeve cuffs; no shoulder loops are worn, but an officer's badge, a small gold tab, is worn on the tip of each shoulder. General officer

FIG. 6.—MILITARY INSIGNIA OF THE EAST GERMAN ARMED FORCES

FIG. 7.—RANK INSIGNIA OF THE FRENCH ARMED FORCES

cap bands are ornamented with gold braid; caps and sleeve cuffs of colonel and below bear gold stripes corresponding to rank: general, five stars; lieutenant general, four stars; major general, three stars; brigadier general, two stars; colonel, five gold stripes with a separation between the third and fourth; lieutenant colonel, same as colonel but the second and fourth stripes are silver; major, four gold stripes, the fourth one separated; captain, three gold stripes; lieutenant, two gold stripes; second lieutenant, one gold stripe.

Noncommissioned officers wear chevrons on their sleeves that are essentially the same as those for the army. (*See* fig. 7.)

U.S.S.R.—*Army.*—Following the Russian Revolution the Red army attempted to abolish distinctions of rank in both uniforms and insignia. However, by World War II, this policy had given way to one of specific styles for various grades, with insignia worn on collar patches and on sleeves. In 1943 new uniform regulations were promulgated by which the Red army restored the once hated shoulder-board type epaulets (*pogoni*) of the Imperial Russian army and reintroduced the tsarist-type standing collar and related insignia. In 1956 the Soviet ministry of defense published new uniform and insignia regulations modifying slightly and refining the system of insignia established in 1943.

Soviet army personnel wear a variety of insignia to indicate rank or grade, arm or service, and in some cases employment. (*See* fig. 8.) Rank or grade is shown by the ornamentation on the coat collar, sleeve cuffs and service cap; by the width and number of stripes on outer trouser seams; and by the arrangement of braid. Rank and grade are also indicated by the number, size and arrangement of stars (for officers) or stripes (for enlisted men) on the shoulder boards. Arm or service is shown by the coloured piping on uniform components, colour of service cap band, stripes and piping on shoulder boards, colour of collar tabs and by emblems on the shoulder boards, collar lapels and collar taps. Variations in the width of shoulder boards, colour of braid, stars and rank stripes distinguish between combatant and noncombatant officers. Further, some emblems indicate the wearer's job within his arm or service.

Dress shoulder boards for all officers except those belonging to the services have silver stars on a gold background. Service branch officers wear dress shoulder boards with gold stars on a silver background. Dress shoulder boards for all army marshals and line generals have a crisscross, gold pattern and red piping; generals of technical troops wear crimson piping. Generals of the medical, veterinary, legal and administrative services wear shoulder boards which are slightly narrower in width than those of other branches.

Shoulder-board insignia denoting rank consist of the following: marshal of the Soviet Union, one large silver star plus national emblem; chief marshal of the arm, one large silver star surrounded by a silver wreath; marshal of the arm, one large silver star; general (*general armii*), four stars; lieutenant general (*general polkovnik*), three stars; major general (*general leitenant*), two stars; brigadier general (*general maior*), one star.

Field grade officers are distinguished by two stripes (coloured according to arm or service) down their shoulder boards with medium-size stars on them as follows: colonel, three stars; lieutenant colonel, two stars; major, one star. Company grade officers have one stripe down the centre of their shoulder boards; rank is indicated by small stars as follows: captain, four stars; senior first lieutenant, three stars; first lieutenant, two stars; second lieutenant, one star.

Enlisted ranks wear both dress and field shoulder boards. On the latter, the branch colour is designated by the piping, the background colour of the shoulder board being olive drab. Some field

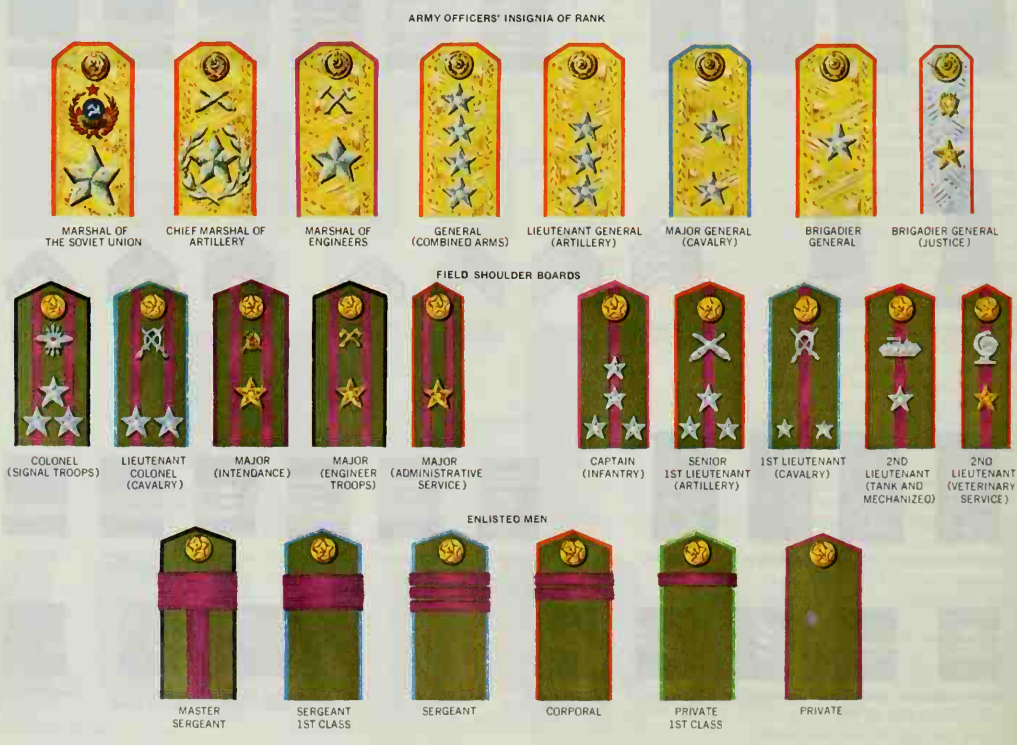

FIG. 8.—RANK INSIGNIA OF THE SOVIET ARMY

shoulder boards have claret-coloured rank stripes; others have gold or silver stripes. Emblems denoting branch of service are not worn by enlisted men on field shoulder boards. The branch colour covers the surface of the dress shoulder board and a gold metallic device (except veterinary soldiers who wear silver) denotes the branch. Black piping is worn on the dress shoulder board with the exception of artillery, armour, motor transport, medical and veterinary personnel, who display crimson piping. The number and position of the stripes used to indicate enlisted rank are: master sergeant (*starshina*), a broad transverse stripe placed on the portion of the shoulder board nearest the neck, with a medium stripe running lengthwise down the centre of the shoulder board; senior sergeant (*starshi serzhant*), one broad cross stripe placed nearest the neck; sergeant (*serzhant*), three narrow cross stripes; junior sergeant (*mladshi serzhant*), two narrow cross stripes; private, first class (*yefreitor*), one narrow cross stripe; private (*ryadovoi*), no stripes.

The colour of the arm or service is displayed on the collar tabs, on the upper edges of collars, on sleeve cuffs, on headdress and on trouser seams. In addition, the colour is also used to form the stripes and piping on dress shoulder boards.

Soviet army paratroopers and antitank personnel are regarded as specialists. A paratrooper wears an outline of a white parachute with a red star above the canopy on a blue diamond-shaped field; the antitank soldier wears crossed cannons on the left arm. Other specialist insignia are worn on the right breast of the uniform.

Air Force.—Soviet air force insignia follow the army pattern, with sky blue as the branch colour.

Navy.—Insignia of commissioned officers generally follow those of the United States. For example, a star is above the top stripe for all commissioned ranks. Sleeve insignia of line officers and those of the naval engineer service are: admiral of the fleet, one broad and four medium-width gold stripes on the sleeve; admiral, vice-admiral and rear admiral each has one less medium stripe; captain, one broad stripe; commander, four medium stripes only; subcommander, three medium stripes; lieutenant commander, two medium stripes and one narrow stripe; senior lieutenant, two medium stripes; lieutenant, one medium and one narrow stripe; junior lieutenant, one medium stripe. Commissioned naval officers also wear shoulder boards patterned after those of the army.

Japan.—*Army.*— General officers of the ground self-defense force are identified by polished silver stars (with rounded points) worn on the collar of shirt or blouse. All other officer grades wear metallic insignia with a dull silver finish. A lieutenant general wears three large stars; a major general wears two. Field and company grade officers wear their rank insignia on the uniform collars; the stars are of medium size and are mounted on a metal plate. A colonel wears three stars; a lieutenant colonel, two; a major, one.

Company officers have small silver stars on one end of the metal plate and embossed gold bands on the other end. A captain wears one star and three gold bands; first lieutenant wears one star and two gold bands; second lieutenant, one star and one gold band. Noncommissioned officers' insignia are on the same type of silver metal plate with black stripes grooved in it as follows: master sergeant, three stripes; sergeant, first class, two stripes; sergeant, one stripe. Privates wear gold chevrons (on green background) on both sleeves between the elbow and shoulder as follows: leading private, three chevrons; private, first class, two chevrons; private, one chevron; recruit, one gold bar.

Navy.—Rank and insignia of the Japanese maritime self-defense force follow the U.S. navy pattern. Commissioned officers wear gold stripes on sleeve cuffs or shoulder boards; the device above the stripes is a gold-lace cherry blossom. The chief of the maritime staff wears a special, more ornately designed blossom. A vice-admiral wears one broad and two medium stripes; rear admiral, one broad and one medium stripe; captain, four medium stripes; commander, three medium stripes; lieutenant commander, two broad stripes with one narrow stripe centred; lieutenant, two medium stripes; junior lieutenant, one medium and one narrow stripe; ensign, one medium stripe. Chief petty officer wears three gold chevrons with cherry blossom above rounded top of insignia; petty officer, first class, blossom, with two chevrons; petty officer, second class, blossom, one chevron; petty officer, third class, three red chevrons topped by pink cherry blossom; seaman, three red chevrons without blossom; seaman apprentice, two red chevrons; seaman recruit, one red chevron.

On less formal uniforms, silver metallic rank insignia are worn on both shirt collars by all ranks down to and including petty officer, second class: vice-admiral, three large blossoms; rear admiral, two large blossoms; captain, three small blossoms on an oblong plate; commander, two small blossoms on an oblong plate; lieutenant commander, one small blossom on an oblong plate; lieutenant, one blossom and three pink stripes on metal plate; junior lieutenant, one blossom, two pink stripes; ensign, one blossom, one stripe. Chief petty officer wears silver plate with three black stripes; petty officer, first class, silver plate, two stripes; petty officer, second class, one stripe. All other ranks wear red chevrons on sleeves, the cherry blossoms being blue for petty officer, third class.

Air Force.—Insignia of the air self-defense force are the same as those of the army except that privates wear silver-thread chevrons instead of gold.

Italy.—*Army.*—Commissioned rank is shown on shoulder loops which are of silver braid for general officers. A lieutenant general wears three gold stars on silver braid; a major general, two gold stars; a brigadier general, one gold star. For prestige purposes, generals holding certain key assignments are permitted to wear four stars set on red underlining. Shoulder loops of other grades are of the same material and colour as the uniform, field grades having gold piping: a colonel wears three gold stars; lieutenant colonel, two gold stars; major, one gold star. Shoulder loops of company grade officers are plain khaki: captain, three gold stars; first lieutenant, two gold stars; second lieutenant, one gold star. Warrant officer rank is designated by longitudinal stripes displayed on the shoulder loop; the highest grade is *Aiutante di Battaglia*, three gold stripes on red background; warrant officer, grade I, three gold stripes; warrant officer, grade II, two gold stripes; warrant officer grade III, one gold stripe.

Enlisted ranks wear sleeve chevrons, point downward, as follows: first sergeant, one wide gold chevron above two narrow gold chevrons; sergeant, one wide gold chevron above one narrow gold chevron; first corporal, one wide black chevron above two narrow black chevrons; corporal, one wide black chevron above narrow black chevron; private, first class, one wide black chevron. Specialist (armourer, parachutist, tank driver, etc.) insignia are worn just above the chevron. Lapel patches are worn by all ranks. The colour of three-pointed lapel insignia indicates the regiment or other assignment in cavalry; the colour and combination of colours of two-pointed insignia shows the regiment or other assignment in infantry or tank corps; the colour or combination of colours of one-pointed lapel insignia indicates arm, service or regiment of any other branch.

All ranks wear metal cap insignia designating arm or service and general officers wear the same distinctive cap insignia: lieutenant general, gold; other general officers, silver.

Navy.—Commissioned rank is indicated by gold braid on cuffs and by gold stars on shoulder boards. A vice-admiral wears five gold stripes, the upper one with curl, the lower one waved; a rear admiral wears the same with one less stripe; commodore, same as rear admiral with one less stripe; captain, one broad stripe surmounted by three narrow, the upper one with curl; commander, same as captain, with one less narrow stripe; lieutenant commander, same as for commander, with one less narrow stripe; lieutenant, three narrow stripes, upper one with curl; lieutenant junior grade, same as for lieutenant, with one less stripe; ensign, one narrow stripe with curl. Chief petty officers wear the following on their shoulder straps: class I, three gold stripes; class II, two gold stripes; class III, one gold stripe. Seamen are identified by chevrons, point downward, on their sleeves: sergeant, one broad on top and two narrow chevrons below; petty officer, one broad and one narrow gold chevron; first corporal, one broad red and two narrow stripes; seaman, first class, one narrow red stripe.

Air Force.—Commissioned rank is shown by gold patches on the

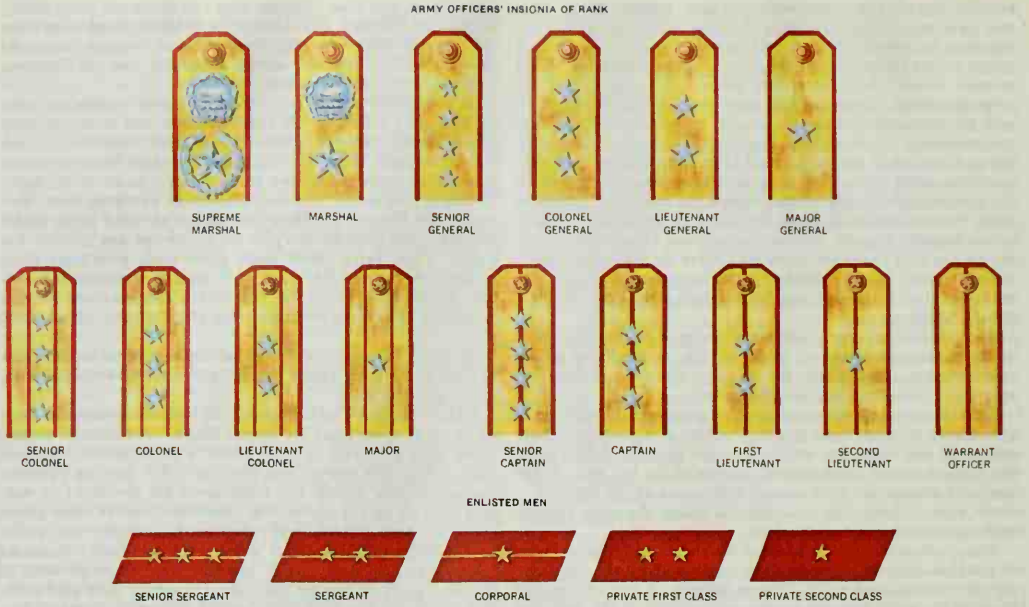

FIG. 9.—RANK INSIGNIA OF THE CHINESE COMMUNIST ARMY

cuffs; the patches are similar in design to those of the navy except that the curl is diamond-shaped. A lieutenant general wears five gold stripes of medium width, the upper one curled in a diamond shape, the lower one waved; major general, same with one less stripe; brigadier general, same as major general with one less stripe. Commissioned officers wear a shoulder strap with gold spread wings inside gold piping. Enlisted men wear rank insignia on shoulder loops.

Warrant officers are distinguished by stripes; other ranks by chevrons. *Aiutante di Battaglia,* three gold stripes with gold star superimposed; warrant officer, class I, three gold stripes; class II, two gold stripes; class III, one gold stripe. First sergeant, one broad and two narrow gold chevrons; sergeant, one broad and one narrow gold chevron; first corporal, two broad and one narrow red chevron; corporal, one broad and one narrow chevron.

Republic of China.—*Army.*—General officer grades are indicated by five-pointed gold stars worn on both the right and left collar of the shirt or on both shoulder loops of the coat. Stars for generalissimo and general, first grade, are linked in a circle; the three stars of general, second grade, in a triangle—for the collar insignia. However, when worn on shoulder loops the stars are in line: generalissimo, five stars; general, first grade, four stars; general, second grade, three stars; lieutenant general, two stars; major general, one star.

Field grade officers' rank insignia consist of various sizes and numbers of gold plum blossoms worn on the right collar of the shirt or on both shoulder loops of the coat. A colonel wears three plum blossoms; they are linked in triangular fashion if on the collar, in line if on the shoulder loop. A lieutenant colonel wears two plum blossoms, a major, one. Company grade officers wear a varying number of parallel gold bars in the same fashion as field grade insignia; captain, three bars; first lieutenant, two bars; second lieutenant, one bar. There is no rank identification for junior lieutenants and warrant officers. When rank insignia are worn on the shirt, field and company grade officers wear branch of service insignia on the left collar.

Noncommissioned officers wear metal chevron plate badges on the left sleeve just below the uniform shoulder seam. No rank identification is worn by enlisted men below corporal. A master sergeant wears a red metal badge edged in gold, with three gold chevrons above a gold plum blossom, below which are from two to four gold horizontal bars, depending on the pay grade; sergeant, first class, two green metal badges edged in gold, with three gold chevrons and three gold horizontal bars below the plum blossom; sergeant, green badge with three chevrons and two bars; corporal, same as sergeant but with only one gold bar.

Metallic branch of service insignia is generally patterned after that of the U.S. army. General officers wear plum blossom insignia in lieu of specific branch insignia.

Navy.—The system of rank identification generally adheres to that of the U.S. navy. For line officers a small circular wreath of rice stalks is worn above the sleeve cuff stripes in lieu of the star of the U.S. navy. On the shoulder boards the Chinese National sun insigne is worn between the button and the rank insignia for all line officers. Flag officer shoulder boards are gold with silver stars and insignia, and black piping on sides.

Air Force.—Rank insignia worn on the shoulder loop of the blouse consist of a varying number of wide and narrow gold bars, a spread-winged eagle being near the button end of the epaulet: general, two wide and three narrow bars; lieutenant general, two wide and two narrow bars; major general, one narrow and two wide bars; colonel, one wide and three narrow bars; lieutenant colonel, one wide and two narrow bars; major, one narrow and one wide bar; captain, three narrow bars; first lieutenant, two narrow bars; second lieutenant, one narrow bar; warrant officer, no rank insignia.

In lieu of shoulder loops the same rank insignia is worn on the right collar of summer uniform shirt with specialist identification on the left collar; warrant officer wears specialist identification on both collars. Specialist insignia: for general officer, a five-pointed gold star with plum blossom, centred; pilots, spread wings with a three-bladed propeller, centred; mechanic, aircraft engine and two-bladed propeller; other specialist insignia follow U.S. army patterns.

While insignia is prescribed for enlisted airmen it is seldom

worn. Instead airmen wear their name and rank written in Chinese characters on a cloth tab worn on top of the left breast pocket.

Communist China.—Up to and after its conquest of the China mainland in 1949 the Communist or People's Liberation army used no metallic badges or other insignia indicating military rank or branch of service. Commissioned officers could be recognized at times by the type of weapons carried, by coloured arm bands either worn on the right arm or wrapped around the butt of their pistols. The higher ranking officers could often be recognized by the presence of armed guards accompanying them. This largest Asiatic army at the turn of the mid-20th century exerted great efforts to conceal the identity of its commissioned and noncommissioned leaders. However, in 1956 the armed forces of Communist China adopted a new uniform system incorporating shoulder boards and insignia designating ranks and branches of service. This system was generally patterned after that of the Soviet armed forces. (*See* fig. 9.) In May 1965 the Chinese government announced that all insignia of rank in the Chinese army would be abolished and that henceforth generals would be indistinguishable from privates. The announcement said that all army uniforms would be alike and that soldiers would wear no insignia except a red star on their caps and a red flag on their collars.

Army.—All commissioned officers of the army wore shoulder boards of Soviet style except that branches of service were not indicated by coloured piping; both the stripes and piping were red. Shoulder boards had solid interwoven gold surfaces with rank insignia superimposed. For general officers, combat arms and political officers the shoulder boards were gold with silver stars superimposed; for administrative and technical staff officers they consisted of a gold background with gold stars. The designs were as follows: supreme marshal, one large star wreathed by silver pine sprays, and the national seal; marshal, same as supreme marshal less the wreath around the star; senior general, four small stars aligned down the centre of the shoulder board; colonel general, three medium stars; lieutenant general, two medium stars; major general, one medium star.

All field grade ranks had shoulder boards bearing two centre red stripes between which stars were placed as follows: senior colonel, four small stars; colonel, three stars; lieutenant colonel, two stars; major, one star.

Company grade shoulder boards had one centre stripe of red. Rank was distinguished by stars ranging from four stars for senior captain to one star for second lieutenant. Enlisted men wore their rank insignia on red collar tabs in the shape of parallelograms. A single, gold horizontal centre stripe on the tab identified the three top grades: senior sergeant, three stars; sergeant, two stars; corporal, one star.

Navy.—Shoulder boards and rank insignia were the same as those of the army except that the stripes and piping were black. The collar tabs were black with white or silver piping; an anchor was in the centre.

Air Force.—Insignia were the same as army insignia except that collar tabs and shoulder-board stripes and piping were sky blue. The collar tabs bore a set of wings in the centre.

INSOLATION, the amount of solar radiant energy received in a given time on a unit horizontal area at any specified place on the surface of the earth or in the atmosphere. It is usually expressed in totals for periods of a day, a week, a month or a year.

Insolation generally denotes the actual amount of energy received after depletion by the atmospheric gases, dust and clouds, although it can express a hypothetical condition, such as the energy received through a perfectly transparent atmosphere.

(H. R. B.)

INSOMNIA, or the inability to sleep adequately, is a common symptom in modern life and varies greatly in degree. Every individual case must be investigated carefully on its own merits; the responsible causes may have a bodily basis or may exist in the mind. *See* SLEEP.

INSPIRATION, in religion, the experience of a possession by the divine that enables the inspired person to see and communicate supernatural truth. The Delphic oracle among the Greeks and the inspired shamans among various peoples have been thought to have an insight into the future and into other divine mysteries (*see* ORACLE; SHAMANISM; SIBYL). For Judaism, Christianity and Islam, the idea of inspiration has been largely (though not exclusively) connected with the sacred books of these religions. Differ though they would about the subject of the sentence, all would concur in the statement of the New Testament, "All scripture is inspired by God." Outside the language of organized religion, the concept of inspiration today is largely aesthetic; this is a secular reflection of the invocation of the Muses in the Greek and Latin epics. When theologians have taken inspiration to mean that the prophet completely loses his individuality, the infallibility of God has been attributed to the scripture as well—a position that has occasioned much controversy among both Jews and Christians since the 18th century. *See* also PROPHET.

INSTALLMENT CREDIT. Installment credit, or hire purchase, as it is known in Great Britain, is the means by which a large part of the durable consumer goods of industrial nations is paid for. Wherever automobiles, refrigerators, laundry equipment and other such products play an important role in the lives of the people, installment credit is a large item in the financial structure of the country. In all the wealthy countries of the world, the greatest single use of installment credit is for the purchase of passenger automobiles. In the United States, for example, beginning in the 1920s, and with the exception of the period immediately after World War II, from 60% to 70% of automobiles have been bought on the installment plan and automobile credit constitutes about 40% of total consumer installment credit outstanding. Installment credit may also be used for other exceptionally large expenditures, such as tax payments, insurance premiums, travel, Christmas expenses and unpaid bills. Business credit may also be repaid by installments. In the 20th century, banks and other financial institutions have made a large number of business loans repayable in installments over several years. In some countries a limited amount of small loans to businesses has been included in the installment credit statistics. In the United States every attempt has been made to confine the concept and statistics of installment credit to the consumer segment of the economy.

Installment loans are repayable at regular intervals over a specified period of time. In the extension of such credit, the contract sometimes provides that the goods purchased will not become the legal property of the purchaser until every installment has been paid, hence the concept of hire purchase. As a rule, in case of default, all previous payments are forfeited to the lender and he may also take possession of the goods. The British Hire Purchase acts of 1938 and 1954 provided that the seller could not take back the goods without a court order if the purchaser had paid one-third or more of the hire-purchase price.

Installment credit constitutes the great bulk of all short and intermediate household credit in most countries, but households also have other debts that do not provide for regular periodic payments. The total of household debts (exclusive of house mortgages) is commonly referred to as consumer credit. Installment credit may be best understood as a major part of all consumer credit.

A large volume of installment credit depends on the employment

and income conditions of the public and on the types of goods which are produced and sold. A population which makes great use of installment credit is one which receives its income in regular periodic amounts, generally in the form of wages and salaries. At the same time, these incomes must be large enough for the population to be able to afford rather expensive durable consumer goods.

Accordingly, installment credit has grown in importance as larger portions of the public became periodic wage and salary earners; as these incomes became large enough to provide for luxury durable goods; as technology provided durable consumer goods; and as the public developed a taste for these goods.

History.—Household or consumer debt is a very old human institution. So long as consumer goods have been articles of commerce, whenever they have been produced by someone other than the consumer and then bought by the consumer, there has probably been consumer credit. But in most cases and throughout most of the world's history, the extension of credit was a personal matter between the seller and the buyer; the debt was not highly institutionalized; and provision for regular periodic repayment was not set forth in a written contract.

Installment loans for the purchase of durable consumer goods, such as furniture, appeared in the 19th century, but first received serious public attention and became of great economic importance shortly after the end of World War I. The rapid increase in sales of passenger automobiles during the 1920s was made possible in large measure by installment credit. Some retailers were able to supply the money necessary to finance credit extensions. In the 1920s, however, there was a rapid growth of a new type of institution known as the finance company.

This type of firm bought instruments of indebtedness from the retailers and collected from the debtors the sums due periodically. Some of these finance companies were from their very inception owned by or closely associated with manufacturers. The most notable example was the General Motors Acceptance corporation (G.M.A.C.), which was organized in 1918. Devoted to financing the sale of General Motors products, it became the world's largest consumer finance organization. Most finance companies, such as the Commercial Credit company of Baltimore, Md., have been independent of both manufacturers and retailers. Some operate on a large scale over an entire country, or even in several countries, while others limit their operations to small areas. In Great Britain and Australia during the late 1950s many finance companies came to be closely affiliated with commercial banks, but such connections did not develop in the United States.

Even before the dramatic increase in installment financing of durable goods in the 1920s another aspect of consumer financing had become a matter of social concern, particularly in the United States. In the 19th century, as an increasing proportion of the population moved into the urban centres and became employed on a wage or salary basis, cash borrowing for consumer purposes grew rapidly in importance. It came to be widely believed that social evils were related to this borrowing and that it should be publicly controlled. Such borrowing by individuals and households was not new, of course, but it was of increasing magnitude and social concern.

The commonest historical form of consumer lending has been pawnbroking; *i.e.*, the lending of money upon the security of household goods or personal effects. As pawnbroking developed in the late middle ages, it soon was subjected to legal controls. Special charters regulated the lenders' responsibility for the safety of the pledged property, the conditions of its forfeiture, the ratio of loans to value of the property, maximum loans to certain classes of people and maximum interest rates. The most frequent maximum interest rate permitted in the late middle ages was 43⅓%, or two pence on the pound per week. Higher rates, however, were not uncommon. (*See* PAWNBROKING.)

Alongside the pawnshops, other moneylenders have operated, advancing funds to wage and salary workers in violation of the usury laws. As a result of increasing concern about social abuses related to this type of lending, various controls have been instituted. In the United States beginning about the second decade of the 20th century, various states undertook to provide for supervised businesses to make small loans. (*See* MONEYLENDING.)

These supervised lenders, known as small loan companies or consumer finance companies, were authorized to make loans in limited amounts, charging rates in excess of those permitted under the usury laws. For example, charges might be at a rate of 3½ cents per dollar per month on amounts up to $300. This charge was supposed to be all-inclusive, providing for investigation, collection, bookkeeping and losses as well as full interest. Such credit has sometimes been criticized on the grounds that borrowers tend to keep themselves perpetually in debt or that lenders encourage them to borrow continuously and unnecessarily. Total loans of the licensed lenders increased from about $20,000,000 in 1917 to about $400,000,000 in 1937. Control of the operations of moneylenders in Britain was provided by acts of parliament in 1900 and 1927. These acts did not provide a legal escape from the usury laws, as was the case in the United States, but provided for controls and limitations in a field that was otherwise not subject to legal limitation.

In the United States, at the same time that escape from the usury laws governing cash loans was being provided by the small loan laws, escape was also provided in the form of durable goods sale credit by the legal doctrine of the time sales contract. Under this doctrine, if a price were placed upon a product to be sold on a credit basis, the difference between this price and the price prevailing if the commodity were sold for cash was judged not to constitute interest and not to be subject to the usury laws. The great expansion of sales of automobiles and other consumer durable goods in the 1920s in the United States was financed in large measure by installment credit without reference to the usury laws of the states.

The rapid growth of consumer credit in the 1920s aroused great public interest and discussion. The development was widely regarded by publicists as unsound from the standpoint of the general economy, somewhat immoral, and unwise from the standpoint of the financial advancement of the borrowers. Despite these widespread attitudes, the desires of the consumer and the salesmanship of retailers and manufacturers resulted in an extremely rapid growth of installment debt. It is estimated that installment debt in the United States rose from $1,000,000,000 in 1920 to $3,000,000,000 in 1929. In response to the widely expressed disapprobation of consumer credit and fears of adverse economic reaction to its growth, some economists and many representatives of finance companies developed theories that consumer credit was necessary for prosperity. They maintained that installment sales credit was necessary for the distribution of the new durable goods among broad groups of the population, and thereby to permit the development of industry on an efficient and highly productive basis.

When the 1929 depression overtook the world, consumer credit proved on the whole a very sound asset. Finance companies survived better than commercial banks, and their assets proved better than the commercial bank assets. Accordingly, the consumer credit business in the 1930s was not the subject of reform legislation, such as that enacted to deal with farm finance, home finance, corporate securities and the stock exchanges. Indeed, the record of consumer credit appeared relatively so good that the commercial banks of the United States, as they rose from the depression, rapidly entered the consumer credit business themselves. By the beginning of World War II they held $1,500,000,000 of installment paper, compared with $1,600,000,000 held by the sales finance companies and $700,000,000 held by other lenders, chiefly the personal finance companies.

But while the depression brought relatively few losses to the holders of consumer credit, it did lead to some critical examination of the subject. Some observers continued to feel that installment credit would contribute substantially to economic instability. Some thought that the collection of funds from the income stream by holders of installment paper during economic depression contributed substantially to a decline in consumer expenditures and to the furtherance of economic collapse. They thought that this might have been a factor in the 1929–33 depression and again in the 1937–38 recession. The completion of some major studies of consumer credit about the end of the 1930s in the United States

helped to form a basis for adoption of special government wartime controls of consumer credit. The lack of confidence in general monetary controls (*see* CENTRAL BANK) that developed during the 1930s created a favourable climate for the consideration of special credit controls when excessive credit expansion threatened upon the outbreak of war.

In the United States special regulation of consumer installment credit was adopted by the federal government for the first time in Aug. 1941. These controls were premised on the lack of effective general credit controls, the desire to channel materials into avenues most necessary for the prosecution of the war and possibly a widespread feeling that consumer credit is unwise from either a personal or social standpoint. Consumer credit controls generally took the form of a down payment requirement or limits on the amount that could be borrowed in relation to the value of the object to be purchased, and limits on the period over which repayment could be extended. In Great Britain the wartime control of consumer credit was a part of price control. It was primarily a control of the rate of finance charge and was chiefly a means of preventing the use of finance charges to circumvent the control of other prices. From 1943 to 1947 an outright prohibition of installment buying or hire purchase trading of most commodities was enforced.

Control After World War II.—The significance of consumer credit control was small during the war because the production of most goods customarily financed with installment credit was brought to a halt. At the end of the war, consumer credit controls took on a new role. As production of consumer goods was resumed, the supply was far less than the demand. Continuation of consumer credit controls helped to limit demand, and this in turn contributed to solution of the problem of allocating the limited supply among consumers.

The British government after the war placed restrictions from time to time on capital issues of hire purchase companies. Such limitations were in operation from 1945 to mid-1954 and again from Feb. 1955 to Feb. 1959. In the United States the government had difficulty deciding when to relinquish control over consumer credit terms. Restrictions were first dropped on Nov. 1, 1947, but in the face of continued inflation, excessive demand for consumer durable goods, and limited general monetary controls, special consumer credit limitations were again put into effect from Aug. 16, 1948, to June 30, 1949.

With the outbreak of hostilities in Korea, regulation of consumer credit was reinstituted in the United States in Sept. 1950 and continued until May 1952. The lack of such controls after that date may be explained in part by the availability of general credit controls, such as the purchase and sale of securities by the central bank, the adequate supply of consumer goods, the difficulties of enforcing such controls and the lack of public agreement that the special control of consumer credit is socially desirable. During the three periods when consumer credit has been under control by the federal government in the United States, administration of the control has been in the hands of the federal reserve system (*q.v.*), implemented by its regulation W.

Just as the United States was abandoning consumer credit controls in 1952, Great Britain was adopting such controls. After 1952 the United States made no use of such regulations, but they played an important role among the economic stabilization instruments exercised by the British government. Credit limitations related to British price control disappeared with the abolition of price control on April 30, 1953. In the meantime, on Feb. 1, 1952, England had entered upon a full-scale control of hire purchase as a means of general economic policy implementation. This type of control was in use the greater part of the time during the following decade, Feb. 1952–July 1954, Feb. 1955–Oct. 1958, and again beginning in April 1960. During the periods when controls were in effect the prescribed time for repayment was usually 24 months, while the initial deposit requirement for automobiles, as an example, varied from time to time from 15% to 50%.

Adoption of consumer credit control in Great Britain after it was abandoned in the United States may have been due to several factors. Other means of general credit control may have been more effective in the United States, where the cash reserve requirements on the commercial banks are very effective. Central bank influence on bank cash reserves in the United States exercises a greater influence on total demand than do the general controls of the Bank of England. Furthermore, the balance-of-trade problem of Great Britain, the extent of economic planning, and controls in other fields have created a greater predilection for specific controls of consumer credit.

The nature and timing of consumer credit controls in Canada for purposes of economic stabilization have been similar to developments in the United States. Indeed, it may be said that the 1950s saw the United States and Canada move away from consumer credit controls as an instrument for procuring economic stability, while many other countries were making substantial use of the device. In Australia hire purchase debt has been largely uncontrolled.

Consumer Spending Decisions.—Installment credit is used for two chief purposes: the purchase of durable goods that are acquired only occasionally, and other large expenditures that cannot readily be paid out of current income. Installment credit enables consumers to spend within a limited time period more than their current income. Purchases made in one month can be paid for out of the income of several months. Tax and insurance payments, annual vacation costs and school tuition payments may be expenditures of such a character.

Consumers may obtain the use of durable goods by a variety of methods: (1) Other assets may be liquidated. (2) Previously accumulated savings may be used, or funds may be saved out of current income until enough is saved to buy the commodity or service. (3) Monthly payments may be made over a period of time. (4) Goods may be obtained by lease or rental. (5) Relatively cheap goods may be bought at the outset and later be discarded or exchanged and better goods acquired as current income permits, the process being repeated indefinitely. If, for example, the $300 that might be required as down payment on a $3,000 car is devoted to purchase of a used car and the amount that would be required to make the monthly payments on the new car are accumulated, a better used car costing $1,500 can be bought after about a year, or a new $3,000 car can be bought after something over two years.

These methods are obviously not altogether distinct or mutually exclusive, but their enumeration is of some value in thinking about the subject of consumer credit. It is scarcely possible to demonstrate that one method of acquiring consumer goods is better than another. Each of them is used, and each best meets the needs of some consumers. It may be argued that the saving up and working up (items 2 and 5 above) methods are best or cheapest, but this suggestion is rather pointless for people who cannot bring themselves to follow the necessary procedures. It may be that for the great bulk of the population it is psychologically impossible either to save up money for major expenditures or to improve methodically the quality or quantity of its durable goods. Yet the consumer may genuinely desire, in spite of costly finance charges, to use installment credit for the high quality durable goods and major expenses, such as vacations, in preference to goods and services which may be simultaneously financed out of current income.

The quantity of consumer credit has depended and will depend on the pattern of goods and services bought by consumers. On the other hand, the availability of consumer credit has determined, to some extent, the pattern of goods and services bought. To the extent that increased levels of consumption take the form of using durable goods, such as automobiles, or engaging in concentrated expenditures, such as vacations or Christmas gifts, consumer credit increases in volume. When expenditures of these types are increasing relative to others, consumer credit will tend to grow more rapidly than income. Consumer tastes, however, may turn toward the leasing of durable goods, recreation, the utilization of services, such as commercial laundries, or the purchase of expendable goods. Such expenditures, which do not involve long-term installment credit, can drop the growth rate of installment credit until it is even with or lower than the growth rate of income.

The length of installment credit used to buy goods such as automobiles bears some relation to the probable length of efficient life of the purchase. A periodic reduction of the debt by a certain amount may correspond roughly to the rate of depreciation. The most common period for paying for a new automobile in the United States in the early 1960s was three years. The longer the average useful life of a product, the greater may soundly be the maturity of the indebtedness.

Many consumers see fit to borrow at interest rates ranging from 8% to possibly 30% while holding liquid assets which yield from 3% to 5%. While such a practice may seem irrational and undesirable, this may not be the practical fact. The consumer may feel that if he borrows, he will be under the discipline of repaying, while if he uses his liquid assets, he will not replace them, and later he will be in a worse financial position than if he had borrowed.

Accumulation of savings and simultaneous borrowing at much higher rates of interest, even from the same institution, may be in a sense costly or wasteful, but this may be the only way in which many households can regulate their spending and contribute to personal peace of mind and maximum satisfaction. The millions of consumers who borrow year after year, even though they have liquid assets, belie the belief that consumer installment credit is a great swindle. In the main, the users like such credit because it enables them to make the best adjustment to the need for financial planning.

Installment credit has sometimes been thought of as a means whereby the individual or family can early enjoy a level of living which is justified only by the anticipation that income will be higher at a later stage of life. However, the major consumer uses of installment credit do not offer much to this end of evening out consumption over an individual's or family's life span. An automobile buyer, 22 years of age, may reasonably expect a higher income at age 35, but the payments on the car must be made within the next two or three years.

Consumer credit does not on the whole provide a means for maintaining a family's level of living in the case of temporary decline of income. Debt is incurred primarily at times of increased employment, increased overtime and rising wage rates. It may be argued that since the monthly payments must on the whole continue to be paid at a time of declining income, spendable funds are made more uneven by installment credit. Some consumer installment debt is incurred at times of reduced income, but such credit plays a small role compared with credit associated with prior or simultaneous increases of incomes. Automobile loans and other types of consumer credit rise in times of increased employment and income; the cash loans of the consumer finance companies, the credit unions (*q.v.*) and the commercial banks also increase most in times of prosperity.

Cost of Consumer Credit.—Consumer installment credit outstanding in the United States by 1963 amounted to about $50,000,000,000, and total finance charges each year were from 15% to 18%. It thus appears that consumers paid about $8,000,000,000 per year for the use of the installment credit method of acquiring their purchases.

The reason for this high cost is that the extension of credit to consumers generally involves cost to the seller or lender. In a few instances, such as the sale of electricity and gas to consumers, either prepayment or credit is technically necessary. In this and some other cases the extension of credit may be less costly to the seller than would collection of cash simultaneously with supplying the goods or service. But, generally speaking, the seller incurs extra costs by virtue of not collecting cash at the time of the sale. In the case of the simple charge account, which is technically payable soon after the receipt of a monthly bill, the costs are generally borne by the seller or, in a sense, by the customers (both those paying cash and those buying on credit). A specific charge is almost always made for all types of installment credit. Compared with other types of credit, the charges for this kind are quite high. While governments and businesses with good credit standing have commonly been able to borrow for 4, 5 or 6 cents per dollar per year, consumers borrowing relatively small amounts, and having a less reliable or undetermined credit status, have commonly paid from 8 to 42 and more cents per dollar per year.

Provision of consumer credit requires large and complicated organizations for investigation of the borrower, keeping records and collecting delinquent accounts. The services of specialized investigation, rating and collection agencies are frequently employed. Provision must also be made for losses. Insurance on the lives of borrowers is frequently provided. Costs vary greatly, depending upon the size of the credit and the character of the borrower. The cost of investigating borrowers and making collections is much less per dollar in the case of large loans than in the case of small loans. Accordingly, the rate of interest charged must be higher on small borrowings than on large. Lenders who confine their business to persons of a relatively high degree of financial responsibility can lend at lower rates than can those who lend to the financially less reliable. This may be one reason why rates charged by the commercial banks are generally less than the rates charged by some other classes of lenders. Credit unions are also able to make small charges on loans because they have lower costs for investigation, collection and loss. Needless to say, it behooves the wise borrower to patronize the lowest-priced lender who will recognize his eligibility for credit. The level of rates paid by consumers for loans has sometimes reflected their unwillingness or inability to bargain or shop around, and some lenders have made very high and, in a sense, unjustified profits. But, in the main, the level of charges has been necessitated by the costs involved.

Consumer Protection.—Historically, consumer credit in the United States has had either to operate illegally or to find some way to avoid the usury laws of most states. Many states have prohibited lending at a charge of more than about 8 cents per dollar per year. Many states have also provided that under government supervision loans can be made by special institutions up to limited amounts at rates above the usury rate. They have generally provided these limits by law rather than by making provision for their determination by administrative action as is generally the case with public utility and other governmental price control.

The other chief way in which consumer credit charges higher than those permitted by the usury laws have been practical has been for the price of goods sold on installments to be higher than the cash price. After World War II, this means of circumventing the usury laws was questioned. Some influential observers came to regard the charges as extortionate; some court decisions indicated that the time price doctrine should not be regarded as a legitimate means of circumventing the usury laws, but as a violation of them. As a result, many states provided by law for interest on sales credit beyond the basic usury limit.

The cost of consumer credit has long been a matter of public and social concern. By way of reform it has been suggested that lenders be required to give better information to borrowers (buyers) regarding credit costs. Information requirements may be of several kinds. The law might require, for example, the quotation of both the credit sales price and the cash sales price. Such is the basic nature of the British acts of 1938 and 1954, while the Advertisements (Hire Purchase) act of 1957 went a step further in controlling publicity. A similar goal is achieved by the laws enacted in about half the states of the United States after World War II. An alternative information requirement may be for the credit cost to be stated in the form of a rate per annum on the unpaid balance. This was the nature of proposed legislation introduced into the U.S. congress in the early 1960s. *See* also MONEYLENDING; PAWNBROKING.

(H. Jo.)

INSTINCT (Latin *instinctus*, "impulse," "instigation"). Popular and literary use of this word is loose: it has been applied to behaviour driven from within ("the mating instinct asserts itself in spring"), to nonlearned behaviour ("the kitten knows instinctively where to find the mother's nipple") and to unconscious or unpremeditated behaviour ("I put my foot on the brake instinctively"). In studies of animal behaviour it has often been applied to relatively complex behaviour which serves a vital end, is at least partly caused by an internal urge and need not be learned. However, it is being realized that the dichotomy instinctive-noninstinctive based on this complex of criteria, or even on any one of them, is not helpful, and modern students of animal behaviour prefer to classify behaviour in a very different way. Yet the aspects mentioned—of adaptedness, of causal organization and of development of behaviour in the individual—remain central themes of investigation.

Adaptedness.—A great many aspects of animal behaviour contribute to survival, and the functional significance of even the most trivial details is the object of research. Most behaviour involves processes in the sense organs, in the nervous system, in the muscles and in hormone-secreting glands, and each of these processes is adapted to contributing toward survival. This is demonstrated in such diverse phenomena as the simple prey-catching movement of the praying mantis, the more complicated action chains such as the "dance" of the honeybee scouts; such complexly adjusted movements as bird flight; the sensory refinements employed in species and individual recognition; symbiotic relationships such as those between flowers and their pollinators; the employment of learning when the situation demands it; the cooperation between individuals in social behaviour; and many other phenomena. In short, the correct functioning of behaviour is recognized as being subject to ruthless pressure of natural selection just as any other life process.

Yet it is obvious from the many things an animal does not do that animal behaviour is remarkably restricted in many respects. Many ground-breeding birds can roll an egg back into the nest, but they invariably use the clumsy method of balancing it against the bill, although a foot or a wing would be better tools and possess the required muscular equipment; gulls, although capable of learning, rarely learn to select a hard substrate when smashing shells by dropping them from the air. Further, unusual circumstances often lead to miscarriage of behaviour and so reveal the limitations of adaptedness.

Thus animal behaviour, while highly complex, variable and adapted, is yet restricted in scope and seems on the whole to be limited by the machinery evolved in adaptation to the demands of survival under natural conditions.

Even the criterion of learned or nonlearned does not allow a simple dichotomous distinction between two types of behaviour. Learning probably applies to more than one type of adaptive change in behaviour machinery during the life of the individual. Learning by imitation is extremely rare in animals; examples from apes have been reported, as they have from some birds which learn their full song by hearing fellow members of their own species, but most animals develop the behaviour typical of their species even when reared in isolation. Isolated canaries, for instance, build typical canary's nests when mature. However, many animals learn by practice. While birds develop the basic pattern of flight without practice, subsequent perfection of skill does depend on it; this may happen extremely rapidly as in cormorants, where one abortive landing attempt may suffice to cause striking improvement with the second attempt. Yet many skills develop without practice; thrushes smash snails expertly when encountering them for the first time.

Even behaviour which is neither imitated nor learned by practice may be subject to learning in another way: it can be conditioned; *i.e.*, change its responsiveness to outside stimuli. Thus pigeons learn to respond to water by drinking, and many songbirds learn to avoid obnoxious insects after one or a few penalized responses. Yet many animals react selectively to appropriate situations the first time they meet them: gull chicks hatched in an incubator respond by crouching to the alarm call of their own species and peck selectively at the parent's bill tip when soliciting food; some butterflies respond selectively to blue and yellow flowers or paper substitutes the first time they feed. In other instances such changes in responsiveness are independent of experience; *e.g.*, the appearance of reproductive responses of many animals upon reaching maturity. Even animals which learn a great deal may fail to apply their ability to learn as widely as human beings would do, and this would seem to indicate in the latter a nonlearned "predisposition to learn"; gulls which learn very readily where their nest is located have no predisposition to learn where to smash their shells.

Thus many behaviour patterns are at the same time learned and nonlearned, the growth of their machinery being the result of complicated interactions between internal and environmental agents. To make a sharp distinction between learned and nonlearned leads to a false dichotomy when applied to behaviour; rather it should be applied to influences governing the development of behaviour machinery, and modern studies try to unravel the interaction of a great variety of inherent and external growth-controlling factors.

Complexity.—Instinctive behaviour has often been considered to be more complicated than simple motor patterns such as reflexes, which have been said to involve "the whole animal." However, this difference is no longer regarded as important, for there seem to be all gradations from simple to complex movements; a frog wipes its side or back with a hind leg when the skin is irritated, and this, although a very simple movement, shows relatively good orientation and is thus more complex than the simplest possible reflex. On the other hand the newly born chicks of many birds crouch at the parents' alarm, and although this is usually called instinctive it is simpler than a frog's wiping reflex.

While it is useful to analyze behaviour into its components, it is not useful to prejudice such analysis by the application of a dichotomy between complex and simple movements and to draw an arbitrary line between instinctive and noninstinctive movements on this criterion.

Causal Organization.—The distinction between behaviour caused by an internal urge and purely reactive behaviour is also considered false, partly because most behaviour is neither purely reactive nor purely spontaneous. Modern research tends to avoid the catchword "instinct" as applied to behaviour patterns, and instead tries to unravel the causal organization of behaviour without prejudice.

Although there is only fragmentary knowledge on the subject, it is already clear that behaviour is organized in hierarchical systems with excitatory and inhibitory relationships of many kinds, and with complex interrelationships between causal chains. These systems are never completely at rest and their excitatory state is subject to continuous change.

The initiation of movements (*i.e.*, the change from one type of activity to another) can be caused by external stimuli or by internal changes or by both combined. Thus many animals of the temperate zones respond to increasing day length (received by light-sensitive organs) by changes in the activity of hormone-secreting glands, which make the animals migrate, select a suitable habitat and proceed with nest building, courting a mate, etc. In all these activities an animal responds in a variety of ways to sensory stimulation, yet a reduction of the sex hormone level (for instance, by castration) abolishes the readiness to respond to many of these very stimuli.

There are many indications that the central nervous system in the intact animal is continually stimulated both by internal agents (humoral, sensory, nervous) and by the "rest output" of peripheral sense organs, and that the machinery of each major behaviour system is never completely at rest. Apart from this, there seem to be humoral and nervous agents which control the general excitatory state. Which behaviour pattern is performed at any one moment seems to depend on the particular unbalance of the conditions facilitating or inhibiting the various systems. On the other hand the external stimuli which, given a certain state, initiate a response are specific. Their effectiveness depends first of all on the sensory equipment of the animal, which is often very different

from human equipment and from that of other species.

Thus bats are sensitive to ultrasonic vibrations; many insects can see ultraviolet radiation; on the other hand, the majority of animals cannot hear properly. Second, the stimulus situation eliciting or inhibiting a particular response is often very restricted: the males of some butterflies, for instance, pursue any moving object when they are in sexual condition, irrespective of its shape and colour.

Which of the available sensory information is responded to is often controlled by the internal condition or "mood," and it is known that this condition can centrifugally affect the responsiveness of sensory systems.

Most behaviour patterns are sequences or chains of simpler movements. Such action chains often begin with searching behaviour which may be spontaneous, and this is continued until the next link in the chain appears. The switch from one link to the next is sometimes caused by internal changes, as has been demonstrated for the mating chain of the male fruit fly, but in other instances it is mainly caused by external stimuli, as for instance in the hunting behaviour of the digger wasp *Philanthus triangulum*. Probably both internal and external control of switching are involved in most instances. Each link itself is a complex movement of variously integrated muscle movements.

Many behaviour chains terminate in an end act such as swallowing food, or in the perception of an end situation such as a shelter out of reach of a predator; the end of a chain is usually marked by an internal change indicated by a reduced readiness to perform the same chain again. This "drive reduction" is often caused by "negative feedback," *i.e.*, information reaching the system as a consequence of the activities performed or of the situation reached, which counteracts the stimuli evoking these activities. Thus reduction of the feeding drive in rats partly results from food stimulating the stomach after ingestion; the readiness to fly in the saturniid moth *Automeris* is reduced by the activity of the central nervous flight mechanism itself.

The part played by feedback systems in behaviour is certainly highly varied and complex, but whether central nervous fatigue or other depletion phenomena can contribute to drive reduction is uncertain.

There is interaction between the major behaviour systems as well as between the various parts of each system, but on the whole major systems inhibit each other mutually, so that at any particular moment the movements of the most strongly aroused system appear to the exclusion of all others. When two systems are simultaneously aroused, various "conflict movements" may occur. These may consist of components of the two patterns combined in a "mosaic"; they may be intermediate or "compromise" movements; the full movement of one pattern may appear with a different orientation; components of both patterns may appear in quick alternation; or a completely irrelevant movement may be performed ("displacement activity"). Interaction on lower levels is responsible for the co-ordination of limbs in locomotion, or even of parts of limbs such as fin rays. Such interaction is partly controlled by the central nervous system, partly by reflex loops, and it may affect both the temporal order and the amplitude of contractions.

Instincts.—Neither innateness, nor spontaneity, nor complexity, therefore, is useful as a criterion for the separation of instinct from other behaviour categories. The term "an instinct," however, has been used as a name for the machinery responsible for the organization of major, functionally unitary behaviour systems, such as feeding, mating, antipredator behaviour, etc., and when used in this way, it is a term comparable to digestive system and merely indicates a phenomenon to be studied. However, in view of the conceptual confusion which the use of such different criteria has created even this usage of the word is increasingly avoided.

Evolutionary Aspects.—Since the growth of the machinery underlying many elements of behaviour, whether affected by the environment or not, is often very stable in successive generations, many motor patterns are relatively constant during evolution, and this is why closely related species are usually similar in their behaviour. Yet evolutionary change does occur and as a consequence no two species behave exactly alike.

Simple mutations have been shown to effect behaviour changes. Much indirect evidence has been collected showing that natural selection can account for adaptive evolutionary change. Conversely, behaviour also affects evolution; such activities as habitat selection, food selection and mate selection seem to have been instrumental in the splitting-up of species.

Animals and Man.—It is too early for an assessment of the ways in which human behaviour has evolved from the ancestral animals' roots. There is, on the one hand, no doubt about the large differences between man and all animals, exemplified by such capacities as foreseeing the future outcome of a planned course of behaviour; man's extremely complicated learning abilities which in turn allow him to pass on acquired knowledge from generation to generation; his tendency to use moral criteria; the retardation of certain aspects of ontogeny which, for instance, prolongs the infantile curiosity or tendency to explore; his ability to utilize specific experience for general purposes; etc.

On the other hand it is becoming increasingly clear that these could well be differences of degree. Man's freedom of action is undoubtedly limited by his evolutionary past. The best way to gain insight in this problem is through comparative studies, particularly of those species most closely allied to man. A major obstacle hampering such work is the fact that man has two sources of knowledge about his own behaviour of which only one can be used for the purpose of comparison. Every human being can observe his own behaviour as if he were an outsider, and record his observations in the same way as behaviour of animals.

Subjective experiences however are not directly observable in animals and cannot therefore be used for comparison. Because our everyday language deals with both types of observables it is not suited as a tool of behaviour research. This is perhaps the main reason why a strictly scientific comparison of the behaviour of animals and man has not yet proceeded very far.

See ANIMAL BEHAVIOUR: *Animal Behaviour Patterns;* PSYCHOLOGY, COMPARATIVE; *see* also references under "Instinct" in the Index.

(N. TS.)

INSTRUMENTATION, in music, is the art of writing parts in the character of instruments forming an ensemble or orchestra and of combining or contrasting the parts so that different textures are produced. The term was first used in French and English in the first half of the 19th century, but it later tended to be replaced by the term orchestration, with which it is synonymous. *See* ORCHESTRATION.

INSTRUMENT OF GOVERNMENT, the name given to the written constitution under which Great Britain was governed from Dec. 1653 to May 1657. It was an attempt to provide a legal basis for government. After the execution of Charles I in 1649 and the suppression of the house of lords, theoretical power was vested in the Rump parliament, effective power in the army, of which Oliver Cromwell was lord general. When the Rump was expelled and the council of state dissolved (April 1653) a second experiment, the parliament of Saints (Nominated, or Barebones, parliament) was equally unsuccessful. On its expulsion in Dec. 1653 Maj. Gen. John Lambert drew up the Instrument of Government under which Cromwell became "lord protector of the Commonwealth."

The Instrument was accepted by Cromwell on Dec. 16, 1653, after certain emendations. Consisting of 42 articles, the Instrument placed the legislative power in the hands of "one person, and the people assembled in parliament"; the executive power was left to the lord protector, whose office was to be elective, and a council of state numbering from 13 to 21 members. Article 33 named Cromwell as lord protector for life but the title was not hereditary. The councilors were appointed for life; 15 were named in the Instrument itself, and Cromwell and the council

were empowered to add six. To fill vacancies parliament was to name six persons, of whom the council would select two, the choice between these two being left to the protector. A parliament was to meet on Sept. 3, 1654, and until that date the protector, with the consent of the council, could make ordinances that would have the force of law. After the meeting of parliament, however, he had no power of legislation, nor had he any veto upon its acts, the utmost he could do being to delay new legislation for 20 days. A new parliament must be called "once in every third year," elaborate arrangements being made to prevent any failure in this respect, and for five months it could not be dissolved save with its own consent. The parliament, composed of a single chamber, was to consist of 460 members—400 for England and Wales, and 30 each for Scotland and Ireland—and the representative system was entirely remodeled. A large majority of the English members (265 out of 400) were to be elected by the counties, where voters must possess land or personal property of the value of £200, while in the boroughs the franchise remained unaltered. In Scotland and Ireland the arrangement of the representation was left to the protector and the council. Roman Catholics and all concerned in the Irish rebellion were permanently disfranchised and declared incapable of sitting in parliament, and those who had taken part in the war against the parliament were condemned to a similar disability during the first four parliaments. The protector was empowered to raise a revenue of £200,000 in addition to a sum sufficient to maintain the navy and an army of 30,000 men, and religious liberty was granted "provided this liberty be not extended to Popery or Prelacy." The chief officers of state were to be chosen with the consent of parliament, and a parliament was to be summoned at once in case of war. The practical effect of the Instrument was to entrust the government of the three countries to the parliament for five months out of every three years, and to the protector and the council for the remainder of the time. Although the Instrument bristled with possibilities of difference between parliament and protector, "it is impossible," as S. R. Gardiner said, "not to be struck with the ability of its framers."

Cromwell governed according to the Instrument until the meeting of parliament on Sept. 3, when he endeavoured to obtain parliamentary sanction for the Instrument. Prolonged disputes followed and he dissolved the parliament on Jan. 22, 1655, without obtaining his object. Regarding the Instrument as still in force, the protector sought for a time to rule in accordance with its provisions; but new difficulties and growing discontent forced him to govern in a more arbitrary fashion. A second parliament met in Sept. 1656, and in the following May Cromwell assented to the Humble Petition and Advice (*q.v.*) which supplanted the Instrument of Government.

INSTRUMENTS, ELECTRICAL MEASURING. Although the electrical power and communication industries are the largest users of electrical measuring instruments, most branches of science and technology depend on electrical measurements for information and for the control of processes and machines. Indeed, it would be difficult to find a research laboratory or a modern factory in which electrical measuring instruments do not, in one way or another, play a vital role.

The varied uses of electrical instruments make it desirable first to consider broadly the principles on which they operate, before undertaking a detailed examination of representative types. This article, therefore, is divided into the following sections and subsections:

I. Electrical Units
II. Absolute Measurements
  1. Lorenz Apparatus
  2. Current Balance
III. Primary Electrical Standards
  1. Standard Ohm
  2. Standard Cell
IV. Indicating Instruments
  A. Current and Voltage Measurements
    1. Potentiometer
    2. Galvanometer
    3. Permanent Magnet Moving-Coil Instruments
    4. Iron-Vane Instruments
    5. Electrodynamic Instruments
    6. Electrostatic Voltmeters
    7. Instrument Transformers
  B. Power Measurements
    1. Electrodynamic Wattmeter
    2. Electrostatic Wattmeter
    3. Bolometer
  C. Energy Measurements
    1. Commutator Watt-Hour Meter
    2. Induction Watt-Hour Meter
  D. Resistance Measurements
    1. Ohmmeter
    2. Wheatstone Bridge
  E. Capacitance and Inductance Measurements
V. Recording Instruments

In most instruments with which electrical current, voltage or power are measured some property of the electrical quantity to be measured is used to evoke a mechanical force, and it is this mechanical force which gives a measure of the electrical quantity. The reaction between a magnetic field and a current-carrying conductor, the attraction or repulsion of electrically charged bodies, are effects that are commonly used to produce such a force. More elaborate means are frequently employed—the heating effect of electrical current in a conductor may be used to raise the temperature of a thermocouple junction, generating an electromagnetic force (e.m.f.) and producing a current in an auxiliary measuring circuit.

Photoelectric and photovoltaic cells are also employed as the sensing elements of electrical measuring instruments. In the measurement of such electrical quantities as resistance, inductance and capacitance, an instrument which utilizes a mechanical force is commonly employed to detect or measure the current or voltage produced in some element of a bridge, potentiometer or other network in which the unknown quantity is being measured by comparison with other similar quantities of known magnitudes. Thus at the heart of most electrical measuring instruments is an element which converts an electrical into a mechanical effect for detection or measurement.

I. ELECTRICAL UNITS

In any measurement, the value describing the quantity must necessarily be assigned in terms of some unit. The units in which electrical quantities are measured have been defined in such a way that they are simply related to the internationally accepted units of length, mass and time (metre, kilogram and second) which form the basis of mechanical measurements. Carl Friedrich Gauss showed in 1833 that magnetic quantities could be measured in terms of mechanical units, and he proposed units (which he called absolute, abbreviation abs.) that were based on mechanical units of length, mass and time.

This concept was amplified by Wilhelm Weber, who showed in 1851 that a complete system of electrical units could be defined in terms of mechanical units. The work of Gauss and Weber formed the basis of a decision by the British Association for the Advancement of Science to define and establish a system of electrical units based on the metric system of mechanical units. Experimental determinations, sponsored by the association, led to the issuance in 1864 of the British association ohm, which was intended to embody the unit of resistance so defined. This unit was found later (1878) to differ by more than 1% from its intended absolute value, but the principles on which the British association units were based gained international acceptance at the Paris Electrical congress of 1881. This congress also described "reproducible" standards which should embody as closely as possible the absolute units of resistance and of current. The ohm was to be represented by the resistance at 0° C. of a column of mercury 106.3 cm. in length, having a uniform cross section (very nearly 1 sq.mm.) and a total mass of 14.4521 g. The ampere

was to be represented by the unvarying current that would deposit 0.001118 g. of silver per second from a silver nitrate solution. Public bill 105, passed by the United States congress on July 12, 1894, made these units, embodied in the reproducible standards and defined in terms of the metric units, the legal units of electrical measure in the United States.

It was recognized that the units embodied in the reproducible standards did not correspond exactly to the absolute units defined in terms of the mechanical units and, to avoid confusion, the former were designated as "international" units. In 1910 representatives of the national laboratories of France, Germany, Great Britain and the United States carried out measurements at the national bureau of standards in Washington, D.C., and assigned values to standard resistors and standard cells from each of the collaborating countries, in terms of international units. From that time until 1948, the 1910 determinations and the international units served the world as the basis for electrical measurements.

A series of determinations of the units of resistance and of current directly in terms of mechanical units, performed in the national laboratories of several countries, culminated in 1948 in the adoption of a new set of absolute units which differed by a few hundredths of a per cent from the previously accepted international units. At the same time the International Committee on Weights and Measures recommended that the metre be used as the unit of length and the kilogram as the unit of mass in defining the electrical units. Thus all electrical measurements derive ultimately from the prototype metre and kilogram preserved at the International Bureau of Weights and Measures in Sèvres, France, and also from the second, defined in terms of the motion of the earth.

While the differences are small between the international units used in measurements before Jan. 1, 1948, and the absolute units employed since that date, these differences are by no means negligible in accurate measurements. The differences in these units are given in the accompanying table.

Conversion Table for Electrical Quantities
International Units to Absolute Units

Resistance	1 int. ohm	= 1.000495 abs. ohms
Electromotive force	1 int. volt	= 1.000330 abs. volts
Current	1 int. ampere	= 0.999835 abs. ampere
Charge	1 int. coulomb	= 0.999835 abs. coulomb
Inductance	1 int. henry	= 1.000495 abs. henrys
Capacitance	1 int. farad	= 0.999505 abs. farad
Power	1 int. watt	= 1.000165 abs. watts
Energy	1 int. joule	= 1.000165 abs. joules.

II. ABSOLUTE MEASUREMENTS

The basic measurements which must be performed to establish the electrical units in terms of mechanical units require the utmost care in the design and construction of the required instruments and a very high degree of skill in their operation in order to assign sufficiently accurate values to the primary electrical standards. These considerations have effectively limited absolute electrical measurements to the national laboratories which, in the various countries, are legally charged with the duty of establishing and maintaining standards.

The national bureau of standards (Washington, D.C.), the National Physical laboratory (Teddington, Eng.), the Physikalisch-Technische Reichsanstalt (Berlin), and more recently the Physikalisch-Technische Bundesanstalt (Brunswick, Ger.) have all carried out such determinations, as have the national laboratories of Japan, the U.S.S.R., Canada and Australia. Their results have been intercompared by means of the standards maintained at the international bureau in Sèvres; and there is no doubt that the electrical units are closely the same throughout the world.

The absolute determination of two of the electrical units, the ohm and the ampere, permits the assignment of values to all the others through simple relationships, such as Ohm's law. Hence, all of the important absolute measurements have been either ohm or ampere determinations. There are various ways in which the ohm and ampere can be determined in terms of length, mass and time; a single example of each will serve to illustrate the principles involved.

1. Lorenz Apparatus.—This device, sometimes used in the ohm determination, is one of the simplest to describe. It consists of a metal disk which rotates in the magnetic field of a coaxial cylindrical coil that carries a current I. If M is the mutual inductance between the coil and disk (the magnetic flux through the disk for unit current in the coil) and n is the number of revolutions per second of the disk, any radius of the disk cuts across the whole flux MI each revolution or MnI lines of force per second. This, by definition, is the e.m.f. $E = MnI$ developed between the centre and edge of the disk. If the current in the coil also passes through a resistance R it develops a potential difference $V = RI$ between the terminals of the resistor. The e.m.f. E is compared to the potential difference V by opposing them to each other with a galvanometer as the detector of their difference. When the speed of the disk is varied, a speed can be found at which $E = V$ or $MnI = RI$, so that $R = Mn$. The mutual inductance M is a constant of the apparatus and can be computed from the dimensions and number of turns in the coil and the diameter of the disk. It will be observed that resistance has been determined as the product of a calculable mutual inductance and a frequency (revolutions per second).

Other ohm determinations have employed different forms of calculable mutual inductors or calculable self inductors, but in each instance resistance is determined as the product of an inductance that can be calculated from measured coil dimensions (length) and a frequency (time). It should be noted that the combination of a calculable capacitance and a frequency may equally serve to determine resistance as a function of length and time.

2. Current Balance.—The current balance, used in absolute ampere determinations, is an instrument in which the force between current-carrying conductors is measured. In one form the balance has a coil of wire suspended from one arm of an accurate equal-arm beam balance. This coil carries the current I to be measured. It is free to move in the field of a coaxial fixed coil which carries the same current.

The force between the fixed and movable coils is $F = I^2 \partial M/\partial X$, where $\partial M/\partial X$ is the rate of change of their mutual inductance with displacement along the line of motion. The weight of the movable coil (in the absence of current) is counterweighted at the opposite end of the balance beam, and the force, upward or downward between the coils when carrying current, is balanced by an added mass m on the appropriate balance arm. This force is mg, where g is the acceleration of gravity at the place where the experiment is performed. The two forces being equal, we may write

$$I\partial M/\partial X = mg \text{ or } I^2 = \frac{mg}{\partial M/\partial X}$$

The coils are so constructed that the value of $\partial M/\partial X$ can be computed from measurements on the coils. It should be noted that the current is measured in terms of mass, length and time.

Because the measured current exists only at the time of measurement, the experiment is used in practice to assign a value of e.m.f. to a standard cell by opposing this e.m.f. by an equal potential difference IR, developed by passing the measured current I through a resistance R of known value.

Thus, both an absolute ohm and an absolute ampere determination are required to assign an e.m.f. value to the cell; but the combined determinations yield two physical standards (a standard resistor and a standard cell) in terms of which the electrical units are always available in the intervals between absolute determinations.

III. PRIMARY ELECTRICAL STANDARDS

Although the values of the electrical units are initially assigned through absolute ohm and ampere determinations, they are preserved and made continuously available in the various national laboratories in terms of groups of 1-ohm resistance standards and of standard cells of known e.m.f. These groups of resistors and cells are designed to be as stable as possible and are compared at intervals with each other and with similar standards from other national laboratories to insure that their values remain constant.

1. Standard Ohm.—Manganin is the resistance alloy used in

all standard resistors and in most precision resistors of high quality. It consists of about 84% copper, 12% manganese and 4% nickel; it is characterized by its low temperature coefficient of resistance and its low thermal e.m.f. against copper. Its resistivity is about 25 times that of copper.

The Thomas standard, designed by James Thomas in 1930, has become generally recognized as the most stable of 1-ohm standards. In its construction, bare manganin wire is wound on a mandrel and annealed at 550° C. in an inert atmosphere. It is then slipped on a silk-insulated metal coil form, fixed in place without introducing mechanical strains, and hermetically sealed in a dry double-walled container. After the wire has attained equilibrium with the small amount of air sealed in with it between the double walls of the container, no further change of resistance occurs. A group of 1-ohm Thomas-type standards is used to maintain the value of the ohm at the U.S. national bureau of standards. No member of this group has changed by as much as 1 part in 1,000,000 over a 10-year interval.

2. Standard Cell.—Early attempts to establish a stable reference standard of voltage were not entirely successful. The Daniell cell (1836) had electrodes of copper and zinc with zinc sulfate as electrolyte, and produced an e.m.f. of 1.08 v. However, such cells lasted only a few weeks and were reproducible only to about 1% accuracy.

The Clark cell (1872) used electrodes of mercury and zinc amalgam in a saturated solution of zinc sulfate to produce an e.m.f. of about 1.43 v. These cells were also rather short lived and had a relatively large temperature coefficient of e.m.f. The Weston cell (1892), with electrodes of mercury and cadmium amalgam in a saturated solution of cadmium sulfate, has an e.m.f. of about 1.0186 v. at 20° C. and represents a great improvement over the earlier standards. When properly made from suitably purified materials, Weston cells can be constructed to have the same e.m.f. within a few microvolts, and may be expected to maintain a constant value over many years.

Some of the cells which were constructed in 1906 as part of the primary standard of e.m.f. for the United States are still in use at the national bureau of standards after more than half a century. The e.m.f. of the cadmium normal cell at any temperature t° C. is given by the formula

$$E_t = E_{20} - 0.0000406(t - 20) - 0.00000095(t - 20)^2 + 0.00000001(t - 20)^3$$

When kept in a controlled temperature environment and properly used, the cadmium normal cell is the most accurate standard of voltage known. The average e.m.f. of a group of such cells in a constant-temperature bath is used at each of the national laboratories as the standard of e.m.f.

A second form of cadmium cell having the same electrodes but with an unsaturated solution of cadmium sulfate as electrolyte (becoming saturated at 4° C.) is much used as a standard of e.m.f. for general laboratory and measurement work. It has a useful life of only about ten years, but its temperature coefficient of e.m.f. is much smaller than that of the saturated cell (about $\frac{1}{8}$ as large) and it will tolerate much rougher usage.

IV. INDICATING INSTRUMENTS

In a quite general way, instruments which indicate the value of current or voltage in an electrical circuit have certain features in common. The quantity to be measured is caused to produce a mechanical force on a pivoted or suspended member, tending to rotate it. The rotation is opposed by a mechanical spring, and the equilibrium position of the movable element, where the torque resulting from the action of the electrical quantity is just balanced by the counter torque of the displaced spring, depends on the magnitude of the electrical quantity. This equilibrium position is indicated by a pointer attached to the moving element, and its reading on an appropriate fixed scale is a measure of the electrical quantity.

Such a mechanical system, rotating about a fixed axis under the action of opposing forces, will tend to oscillate about its equilibrium position unless damping means are provided to absorb the energy of motion and bring the system to rest. Two types of damping are regularly used. Magnetic damping utilizes conductors which form a closed electrical circuit and move in the field of a permanent magnet. The motion of the conductor in the field induces an e.m.f., and the resulting current dissipates energy as heat in the resistance of the circuit. The circuit may be the local eddy-current circuit of a metal vane or sheet attached to the moving element, or it may include the coil which forms the moving element (as in a galvanometer) together with the external circuit to which it is connected. Fluid damping makes use of the viscous flow of air (sometimes oil or another liquid) across a moving element to absorb the energy of motion. In practice a vane, attached to the rotating element of the instrument, moves with small clearance in a closed chamber. The air which it compresses ahead of it as it moves flows back over its edge and provides the desired energy absorption. In either fluid or magnetic damping, energy of motion is absorbed by the damping mechanism and dissipated as heat in bringing the moving system to rest. In the design of an instrument, damping is usually adjusted to be somewhat less than critical, *i.e.*, the moving system overshoots its equilibrium position slightly and quickly settles back to its proper indication.

Instruments whose indicating element turns in bearings have additional frictional forces which oppose motion. Because the deflecting torque is always small, it is essential that bearing friction also be minimized, and such bearings usually consist of hardened steel pivots turning in sapphire cup jewels with the bearing contact area held to the smallest value which will support the weight of the moving system. Where friction must be further reduced, diamond pivots in sapphire bearings have been used to advantage. Bearing friction can be avoided altogether by suspending the indicating system from thin metal ribbons or "torsion bands" which also act as the instrument springs. This is done where the deflecting torque is extremely small (in galvanometers) or where the instrument has to endure heavy shock or vibration in use.

A. Current and Voltage Measurements

Instruments used to measure current or voltage have many features in common. In fact, any instrument whose basic response is to current can be adapted to the measurement of voltage and an instrument which responds to potential differences can be adapted to the measurement of current. This follows from Ohm's law, that the voltage E appearing across a resistance R which carries a current I is the product of the current by the resistance $E = IR$. Thus, if a known resistance be connected in series with a current-sensitive device, the response of the instrument is a measure of the voltage across the combination.

Similarly, if a voltage-sensitive device be placed across a known resistance carrying a current, the instrument response is a measure of the current in the resistor.

1. Potentiometer.—The potentiometer is the most precise instrument available for measuring direct current or voltage. It consists of a circuit in which voltages are compared with the known e.m.f. of a standard cell. An elementary potentiometer could be a long uniform slide-wire MN (*see* fig. 1[A]), which carries a fixed current I. If R is the resistance of the wire per unit

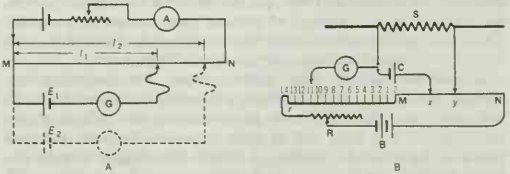

FIG. 1.—POTENTIOMETER: (A) SLIDE-WIRE TYPE; (B) CROMPTON TYPE

length, the voltage difference between two points on the wire separated by a distance l is $E = Rll$. Then if a cell of known e.m.f. E_1, in series with a galvanometer G to detect the presence of any potential difference, is connected to two contacts on the slide-wire and one of them is moved until the galvanometer indicates that the voltages are equal, $E_1 = Rll_1$, where l_1 is the dis-

tance between the contacts at balance.

On substituting another cell of e.m.f. E_2 and moving the contact until a voltage balance is again obtained at a separation l_2, then $E_2 = Rll_2$. If the wire is uniform and the current, measured at the ammeter A, remains constant between the two balances,

$$\frac{E_2}{E_1} = \frac{l_2}{l_1} \text{ or } E_2 = E_1 \frac{l_2}{l_1}$$

The unknown e.m.f. E_2 is thus determined from the known e.m.f. E_1 and the ratio of slide-wire lengths required to balance E_1 and E_2 against the potential drop along the wire.

The potentiometer can be made direct reading and at the same time more convenient to operate by the following modification, known as the Crompton potentiometer (*see* fig. 1[B]). Suppose the slide-wire is 1 m. long, its resistance 10 ohms and it carries a current of 0.01 amp. The total voltage drop along it will be 0.1 v. or 0.0001 v. per millimeter. Then any number of fixed resistors of 10 ohms each can be connected in series to one end of the slide-wire and, for the same current, will each have a voltage drop of 0.1 v.

The diagram of fig. 1(B) shows a potentiometer with such a slide-wire MN, a standard resistance S and a dial of 14 fixed coils, whose current is supplied from a battery B and adjusted to proper value with rheostat R by using a reference cell C. If C were a cadmium cell having an e.m.f. of 1.0187 v., the left-hand contact (on the dial) could be set on the eleventh contact of the dial (1.0 v.) and the right-hand contact at 187 mm. from the left-hand end of the slide-wire (0.0187 v.). When the current is brought to its proper value by adjusting the rheostat R, the total voltage drop will exactly balance the e.m.f. of the reference cell (1.0187 v.), and the potentiometer is ready for use. Any other source of voltage up to 1.5000 v. can now be substituted for C and balanced by varying the positions of the dial and slide-wire contacts. At balance the voltage may be read directly from the dial and slide-wire contact positions.

Higher voltages, up to 1,000 v. or more, can be measured by using a volt box, which consists of a group of series resistors of known ratio such that, when the high voltage is placed across the group, a low voltage (within the range of the potentiometer) appears across a section and is measured. The total voltage is then the potentiometer reading multiplied by the volt-box ratio. For example, a volt box could be made up with 10,000 ohms resistance and tapped at a point 100 ohms from one end. This voltage divider would have a ratio of 100:1 and could be used to measure voltages up to 150 v. on the potentiometer described above. If a current is to be measured, it is passed through a resistance (1 ohm, 0.1 ohm, 0.01 ohm, etc., depending on the magnitude of the current) and the voltage drop across the resistor is measured with the potentiometer. For example, a current of 100 amp. through a 0.01 ohm shunt would develop a voltage drop of 1 v., and this could be measured on the potentiometer.

The potentiometer is not only the most precise of all D.C. instruments, but is also the basic tool in a measurement program. It measures voltage and current in terms of standard cells and standard resistors that need not be more than a single step removed from the primary electrical standards. Simultaneous measurements of current and voltage can be used to measure power, since power is the product of current and voltage in a circuit. Thus, the potentiometer is the instrument with which D.C. ammeters, voltmeters and wattmeters are calibrated.

2. Galvanometer.—The galvanometer, for indicating extremely small currents, is usually a suspension instrument. In its common form, the d'Arsonval galvanometer, the deflecting system consists of a light coil of wire suspended between the pole pieces of a permanent magnet by means of a copper or gold ribbon a few thousandths of an inch wide and less than a thousandth thick. A small mirror, mounted on the coil, serves as an optical pointer and indicates the coil position by reflecting a light beam onto a fixed scale.

Current is conducted to and from the coil by the suspension ribbons, and the reaction of the current in the coil with the radial magnetic field in which it is suspended produces a torque that tends to rotate the system. The action can be likened to that of a tiny motor winding up a spring.

Modern galvanometers may have a sensitivity of as much as 1 mm. of deflection (on a scale 1 m. distant from the mirror) for a current of 0.00001 μamp. (10^{-11} amp.), with a coil resistance of 800 ohms. Current sensitivity is increased by using more turns of finer wire in the moving coil and by reducing the cross section and stiffness of the suspension ribbon.

Galvanometers may also be used for the detection or measurement of very small voltages in closed electrical circuits. In this instance it is advantageous to use a few turns of relatively coarse wire in the moving coil. A galvanometer having a resistance of 12 ohms and a response of 1 mm. for 0.1 μv. (10^{-7} v.) in a 25-ohm circuit is an example of a modern voltage-sensitive instrument. In general, current-sensitive instruments are characterized by relatively high resistance, while voltage-sensitive instruments have low resistance.

In addition to appropriate current or voltage sensitivity, it is important in selecting and using a galvanometer that consideration be given to the resistance of the circuit in which it is to be used. This should be equal to or slightly greater than the critical damping resistance of the instrument in order that the moving system slightly overshoot its equilibrium position and come to rest in the minimum possible time. If the circuit resistance is too low, the galvanometer will be overdamped and its motion will be sluggish; if too high, the galvanometer will be underdamped and the moving system will oscillate about its equilibrium position with gradually decreasing amplitude.

In addition to its use for the detection and measurement of minute currents or voltages of constant value, the galvanometer may be used ballistically to integrate a transient current or voltage pulse of short duration. The electric charge in a capacitor can be measured by allowing it to discharge through a galvanometer and observing the magnitude of the moving system's first excursion from its rest position. The response of the instrument to a current of short duration defines the coulomb sensitivity. The deflection is proportional to the time integral of current, or to electric charge.

Similarly, a voltage pulse arising from changes in a magnetic field linking a coil of wire is a measure of the total change in coupling between the field and coil, the time integral of voltage during the change. This type of response is defined by the e.m.f.-time (or flux-linkage) sensitivity of the galvanometer.

Thus, a galvanometer has four different sensitivities which describe its performance in various applications. It is of interest to note that only one of them, current sensitivity, is completely defined solely by the galvanometer design constants—the strength of the magnetic field in which the coil moves, the area turns of the coil and the stiffness of its suspension. Voltage, coulomb and e.m.f.-time sensitivities are all functions of resistance of the circuit to which the galvanometer is connected. Both steady-state and transient voltage response increase with decreasing circuit resistance, while response to a transient current increases with increasing circuit resistance.

As stated above, the galvanometer and numerous other types of indicating instruments make use of the reaction between a magnetic field and a current-carrying conductor to achieve a measure of the current in the conductor, or of some related quantity. However, it is not essential that the current be carried by an indicating element suspended in the field of a fixed magnet system as is done in the d'Arsonval galvanometer.

Similar response can be accomplished, and with equal sensitivity, by making a magnet the moving element, and conducting the current through fixed coils. In galvanometer applications the chief advantage of this alternative construction is that the suspensions of the moving system, which do not now have to carry current, can be made of extremely fine quartz fibres, with much reduced stiffness. As the response of the indicating system depends on balance between the driving torque (resulting from the interaction of the magnetic fields of magnet and current) and restoring torque (resulting from suspension stiffness), the lower driving torque available in this arrangement is compensated by reduced suspension stiffness.

The principal disadvantage of the moving magnet, fixed-coil galvanometer is that its response is affected by the ambient magnetic field to a much greater extent than is the fixed magnet, moving-coil arrangement. For reasonable performance a moving magnet galvanometer must be elaborately shielded from external magnetic fields by a series of nested enclosures of high-permeability material, and for best results the construction must also be astatic, *i.e.*, the moving magnet and coil system must be arranged in matched pairs in such a manner that the torques resulting from a uniform external field will be in opposite directions and neutralize one another, while the torques that result from the reaction between the suspended magnets and the current in the coil pairs are additive. Despite the high sensitivity that can be achieved with this arrangement, it is little used in modern practice because of the difficulty of achieving adequate shielding from external magnetic fields.

3. Permanent Magnet Moving-Coil Instruments.—This basic class of instruments is used for indicating direct currents and voltages. The indicating system is similar to that of the d'Arsonval galvanometer. A coil with an attached pointer rotates in the field of a permanent magnet. In order that the angular response of the moving system be uniform, the magnet structure is designed so that its field is radial throughout the length of the air gap in which the coil turns.

Another design requirement is that the magnet maintain an unchanging field in the air gap, so that the calibration of the instrument shall not change in time. This requirement leads to the use of the characteristic horseshoe shape for instrument magnets of tungsten or chromium steel, whose length must be very great compared to their cross section for optimum energy storage, and to short thick magnets when dispersion-hardening steels such as alnico are used.

The moving-coil system usually turns on pivots in jewel bearings, and the attached pointer moves over a graduated scale from which the value of current or voltage is read. In this construction spiral springs are used to conduct current to the coil and to supply the required counter torque. In some instances the moving system is suspended between taut metal bands which act both as springs and as current leads. This construction avoids the friction of mechanical bearings, and is used in some types of precision instruments.

For low current values (microammeters and milliammeters with ranges up to perhaps 20 milliammeters [ma.]) the current to be measured is carried by the springs and coil of the instrument. Larger currents would produce a significant temperature rise in the springs and alter their stiffness. Consequently, currents larger than 20 ma. are passed through a resistor (or shunt) across which a millivoltmeter is connected in parallel. Thus a voltage-sensitive element, responding to the voltage drop (up to 50–100 mv full scale) across the current-carrying shunt, is used to measure larger currents. Its scale is marked, of course, in terms of current in the shunt. All permanent magnet moving-coil ammeters use such a parallel circuit arrangement. For small currents the shunt may be within the instrument case. For large currents, where a substantial amount of heat must be dissipated by the shunt, it must be external to the instrument.

In measuring voltages it is always desirable that the current drawn by the instrument be small in order to minimize both the power consumed by the instrument and the load it imposes on the voltage source. Hence, for the measurement of direct voltages, a permanent magnet moving-coil system which will attain full-scale deflection with a current in the range from 0.1 to 10 ma. is used together with a series resistor (or multiplier) of such resistance that the rated voltage of the instrument produces full-scale current. The instrument scale is marked to read the voltage impressed on the combination of moving element and multiplier. Here also, for low and moderate ranges where the power dissipation is small, the multiplier is incorporated into the instrument case; for high ranges the multiplier is frequently external and must be connected in series with the instrument.

Permanent magnet moving-coil instruments respond to the average value of their operating current and so, while they are ideally suited to the measurement of unidirectional currents and voltages, they cannot be directly used for the measurement of alternating currents, which vary rapidly and continuously between equal values in opposite directions, so that the average value is zero. The torque produced on the moving system of such an instrument would reverse in direction with each reversal of current, with the result that the coil could never move from its zero position, or at most would vibrate about it with small amplitude. However, such indicating systems can be adapted to the measurement of alternating currents by one of several devices.

Rectifier Instruments.—Copper oxide and other types of dry rectifiers can be used in combination with permanent magnet moving-coil indicating systems in the construction of voltmeters and low-range milliammeters for measuring alternating voltages and currents in the power and audio-frequency regions.

A full-wave four-element bridge-type rectifier, connected as shown in fig. 2, is used with the A.C. input impressed across one

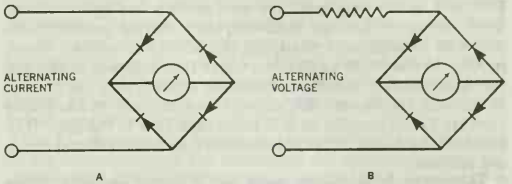

FIG. 2.—RECTIFIER INSTRUMENT CONNECTIONS: (A) MILLIAMMETER; (B) VOLTMETER

bridge diagonal and the D.C. milliammeter connected across the other. For voltmeters a resistance of appropriate value is connected in series with the input terminals. The rectifier assembly consists of copper disks, $\frac{3}{16}$ in. or less in diameter, with a surface layer of cuprous oxide, assembled into a stack with appropriate electrodes and sealed in a housing. Small disks are used to keep the current density high in the rectifying surfaces (with low consequent forward resistance), and to keep the capacitance of the bridge low in order to reduce the errors of the instrument at the higher audio frequencies. The milliammeter responds, as would any D.C. instrument, to the average value of the current in its moving coil.

For engineering applications the root-mean-square (r.m.s.) value of current or voltage is generally desired, and consequently the scales of most rectifier instruments are marked in terms of r.m.s. values for an assumed sine-wave input. This scale convention coupled with the actual response to average rather than r.m.s. values results in errors of indication on nonsinusoidal inputs. Also both the forward and reverse resistances of the rectifier elements have large but different temperature coefficients of resistance, resulting in a substantial temperature coefficient of indication. Because of their frequency, wave form and temperature errors, rectifier instruments must be considered as devices of low or moderate accuracy. However, they are very rugged, have high sensitivity and are quite suitable for audio-frequency applications in which accuracy requirements are moderate. Also, the D.C. mechanism is directly available when the rectifier is disconnected. Consequently, this type of instrument is widely used in compact test sets with which, by suitable switching, both A.C. and D.C. currents and voltages can be measured.

Such instruments, with a large number of A.C. and D.C. current and voltage ranges, are very convenient for use on the test bench, in electronics laboratories and in servicing electronic and electrical equipment.

Thermocouple Instruments.—The permanent magnet moving-coil systems for alternating current and voltage measurements are also employed in thermocouple instruments. The current is passed through a heater element (usually a fine wire) in thermal contact with one junction of a thermocouple. The thermocouple, consisting of wires of two different metals or alloys joined together in series, has the property of generating a small e.m.f. where the junction points between the dissimilar metals are at different temperatures. Thus, at the thermocouple junction in contact with

the hot wire, an e.m.f. is generated which is proportional to its temperature rise and hence to the square of the current to be measured. The thermocouple circuit is completed by a low-range D.C. millivoltmeter and its scale is marked in terms of the r.m.s. value of heater current.

A thermocouple voltmeter uses the same arrangement but with the addition of a resistance in series with the heater element. In this instance the millivoltmeter scale is marked in terms of the r.m.s. input voltage across the resistor-heater combination. Since the instrument responds to the square of the heater current, no wave form error results on nonsinusoidal inputs.

Depending on the size and resistance of the heater element, current-indicating instruments are made with full-scale ranges from 1 ma. to 100 amp. At higher current ratings a thin-walled tube rather than a wire is used as the heater element. With proper heater construction and thermocouple arrangement, such instruments can be used to indicate current with negligible error from D.C. to 1 mc. in frequency, and with small errors up to 100 mc. They are much used for radio-frequency current measurements and, with suitable precautions, can also be used as transfer instruments. In this latter application, where their response is identical for equal values of direct or alternating current, they can be used to calibrate instruments that respond correctly only to alternating currents, *i.e.*, to transfer an A.C. calibration back to the basic D.C. standards by means of the potentiometer, standard cell and standard resistors.

Thermocouple voltmeters make use of heater elements of low current rating (a few milliamperes) and are useful from D.C. up through the audio-frequency range without serious error. With properly constructed resistance multipliers, having negligible inductive or capacitive residuals, the frequency range can be extended upward to 1 mc. or more. These instruments can also be used for transfer measurements from direct to alternating voltages if proper precautions are observed.

Electronic Voltmeters.—Vacuum-tube voltmeters also make use of D.C. indicating elements. In one of its simpler forms, such a voltmeter has an input circuit in which a miniature diode is arranged to charge a capacitor. A low-range D.C. milliammeter or a microammeter is connected with a high series resistance across the capacitor, and the current is a measure of the input voltage. If the discharge time of the resistor-capacitor combination is long compared with the period of the input voltage, the current in the D.C. meter is practically constant, and the response depends on the peak value of the input voltage.

Thus the lower frequency limit of the arrangement is determined by the time constant of the discharge circuit; the upper frequency limit for operation without substantial error is fixed by the distributed parameters of the input circuit and may be 100 mc. or more. It is fairly general practice to mark the scale in terms of r.m.s. values for an assumed sine-wave input and, as the response is to peak values, wave-form errors will appear on a nonsinusoidal input.

It should be noted that in the above arrangement, as is usual for indicating instruments, the power required to accomplish and maintain a deflection is supplied by the source on which a measurement is being made. This is not true of all electronic voltmeters. Starting with the same input circuit, a diode and capacitor, the voltage of the charged capacitor may be impressed on the grid of a triode or a more elaborate vacuum tube which acts as the initial element of a D.C. amplifier.

In such an arrangement the auxiliary power source, which is an integral part of the amplifier, supplies the power to operate the indicating instrument, and the drain on the measured source is extremely low. This is of great importance if the voltage from a high-impedance source is being measured.

There are many types of electronic voltmeters that use elaborations of the basic circuits above. The performance of the amplifier may be stabilized by a feedback loop of appropriate design. Also, such a circuit may be preceded by an attenuator for multirange operation, or by a preamplifier to extend the range of measurements to lower voltages. A typical commercial electronic voltmeter has an input impedance of 8 megohms at low frequencies, an input capacitance of 10 micromicrofarads, ranges from 0.1 to 150 v. and a frequency influence of no more than 3% up to 50 mc. and 12% at 100 mc.

4. Iron-Vane Instruments.—These are the commonest type of ammeters and voltmeters for laboratory and switchboard use at commercial-power frequencies. Such instruments can be built to measure current or voltage to all the accuracy needed for most engineering work, and still be produced more cheaply than any other type of A.C. instrument of equal accuracy and ruggedness. A vane or plate of high-permeability steel, together with spring, pointer and damping structure, forms the moving element of the instrument. This vane is situated in the field of a stationary electromagnet consisting of a coil of wire and, usually, a second iron vane which is fixed in position. The excitation of the electromagnet derives from the current or voltage to be measured, and the motion of the vane, when the electromagnet is excited, is always such as to increase the flux through it. Thus the torque produced by the reaction between the magnetic fields of the stationary and moving elements is in such a direction as to increase the inductance of the combination.

The energy stored in the magnetic field of a current-carrying inductor is proportional to the second power of the current, and it follows that the torque in the moving element increases with the square of the current in the fixed coil. Hence the response of the instrument is to r.m.s. current or voltage.

It should be noted that in this construction the measured current does not go through the moving element, and the sole function of the instrument spring is to provide the required counter torque. Approximately 200 amp.-turns are required to produce a deflection of 90° in the actuating coil of a portable instrument with a 5-in. scale. The coil, about 1 in. high, may be wound with the needed turns of appropriate size wire for any desired range; *i.e.*, 40 turns for a 5-amp. instrument or 200 turns for a full-scale current of 1 amp. For the highest range that is possible in a 200 amp.-turn instrument—200 amp.—a single turn casting is used. For a milliammeter, a coil of 4,000 turns will give a full-scale sensitivity of 50 ma.; such a coil, connected in series with an appropriate resistance, is used in a voltmeter. Throughout the entire group of instruments the iron structure and moving system are identical.

The operating magnetic field of an iron-vane instrument is relatively small, at most 60–75 gausses at full-scale deflection. As a consequence, moderate external fields will have a significant effect on the deflection unless the entire operating system, coil and vanes, is enclosed within a magnetic shield. For example, an error of as much as 10% may result from operating an unshielded instrument in a 5-gauss field; but the corresponding error in a properly shielded instrument may be no more than a few tenths of 1%.

While the most common use of iron-vane instruments is at commercial-power frequencies, they are by no means limited to these applications. They can be used effectively at frequencies well above 1 kc. However, the frequency range over which an individual iron-vane instrument may be employed without significant errors of indication is quite limited; both ammeters and voltmeters should be calibrated at a frequency that does not differ by more than 10% from that at which they are to be used.

The change of response of an ammeter with frequency results principally from eddy currents in the iron vanes and other metal parts of the structure within and around the coil. These eddy currents, whose magnitudes are proportional to the square of the frequency, give rise to local magnetic fields that modify the reaction between the iron vane and the field of the coil carrying the measured current. Thus, the torque of the moving system and the indication of the instrument for a given current are functions of frequency. This eddy-current effect is also present in voltmeters, but here there is another important source of frequency error. The inductance of the instrument's current coil, proportional to the square of the number of turns, becomes quite large in a voltmeter, whose coil may have several thousand turns. Consequently the combined impedance of the coil and series resistance increases substantially with increasing frequency, while

the voltage at the instrument terminals, required to provide operating current in the coil, increases at a corresponding rate.

As the voltmeter scale is marked in terms of the voltage needed at the instrument terminals to produce the operating current, the frequency range of the instrument is limited by the impedance change. The operating range can be substantially increased by shunting a portion of the voltmeter multiplier by a capacitor to compensate for the coil inductance but, since capacitive reactance decreases, there will be an upper frequency limit at which compensation is no longer adequate.

5. Electrodynamic Instruments.—Electrodynamic ammeters and voltmeters are usually made only in the best accuracy classes (laboratory standard and portable standard instruments) and are little used outside the calibration laboratory, although instruments of a similar construction are used almost universally to measure electric power. This is because they are much better adapted to make precise measurements of power than is any other type of instrument, whereas, for current and voltage measurements, the less expensive and more rugged iron-vane instruments are adequate in most engineering work.

Electrodynamic instruments are, however, used in the laboratory to check the calibration of other less precise A.C. ammeters and voltmeters, and to transfer calibrations from D.C. standards to instruments that respond correctly only to alternating currents and voltages.

Electrodynamic instruments make use of the magnetic fields of two sets of coils, one fixed and the other movable. Each coil carries a current which is a function of the current or voltage to be measured, and the reaction between the fields of the fixed and movable coils supplies the torque for the moving system. Here also, as in the iron-vane instruments, the energy storage in the magnetic fields of the coils is proportional to the square of the coil current, and electrodynamic instruments respond to r.m.s. current or voltage.

In the usual construction a moving coil is pivoted or suspended in the field of a pair of fixed coils, and has attached to it springs, pointer and damping vane. The moving-coil current is carried by the instrument springs and is limited to a fraction of an ampere. As the available torque is small, the weight of the moving system must be kept low. The result is a structure that is considerably less rugged than is the moving system of an iron-vane instrument.

The operating field is usually less than 60 gausses for full-scale deflection, and either the entire operating mechanism must be protected by a magnetic shield against external fields or the coil system must be astatic so that the presence of external fields will not result in any net deflecting torque.

In an electrodynamic voltmeter the fixed and moving coils are connected in series to carry the entire current, and a suitable multiplier fixes the voltage range. A low-range electrodynamic milliammeter would also have its coil system connected in series to carry the entire current. However, as the current capacity of the instrument springs limits the moving-coil current, higher current ranges make use of a parallel-coil arrangement. The fixed coils, which can have whatever current capacity is required, carry all but a small fraction of the measured current and have in series with them a resistor of appropriate size and current capacity. The moving coil, also with a resistor in series, is connected in parallel with the fixed-coil-resistor combination. The time constant of each branch of the circuit, *i.e.*, the ratio of inductance to resistance, must be the same in order that the division of current shall not change with frequency. Modern electrodynamic ammeters are seldom built in ranges above 10 amp. A current transformer together with a 5-amp. instrument is generally used for precise measurement of higher currents.

Frequency errors in electrodynamic ammeters arise from two causes. Metal present in coil supports and other parts, and in the instrument shield, will have eddy currents induced in it and will cause a change in deflection with changing frequency, in the same manner as for an iron-vane instrument. However, by proper construction eddy-current errors can be kept to a considerably lower level than is possible in the iron-vane ammeter. In addition to eddy-current errors, another must be expected. Because of the parallel branches, the ammeter coils operate in a closed loop of comparatively low impedance, and the coupling between fixed and moving coils will produce a circulating current in this closed loop, resulting in a torque which is a function of frequency. Frequency errors in electrodynamic voltmeters arise from eddy currents and from the self-inductance of the coil system. These also are similar in kind but smaller in amount than are to be expected in iron-vane voltmeters.

Before using an electrodynamic instrument in transfer measurements, the difference in its performance on D.C. and at the desired frequency should be checked.

6. Electrostatic Voltmeters.—In this type of instrument the deflecting torque results from the action of an electric field on charged conductors (electrodes). Such instruments are useful at low voltages when no appreciable current can be drawn from the circuit. They can also be designed for use at extremely high voltages. In fact the total range of voltage covered, with small errors in measurement, is greater than for any other class of deflecting instrument. They are built regularly in ranges from 50 to 100,000 v. Any good electrostatic voltmeter can be considered as a low-loss capacitor, so that on D.C. voltage, the operating current (after the initial charging current) is merely the very small leakage current required by the insulation resistance of the instrument (which may be as much as 10^{14} ohms).

On A.C. voltages the current is determined by the capacitance of the instrument and the frequency, the operating current increasing with increasing frequency as the reactance decreases. A 15,000-v. instrument, having a capacitance of 20 micromicrofarads, would require 120 μamp. for full-scale deflection at a frequency of 60 c.p.s.

In low-voltage electrostatic voltmeters the fixed and moving systems consist of groups of flat interleaved sector plates. As fixed and movable plate systems are insulated from each other, a voltage impressed between them results in the appearance of charges of opposite sign on the two sets of plates. The force of attraction between these charges produces a torque which is opposed by a spring or, in the case of a suspended system, by stiffness of the suspension bands.

In higher-voltage instruments, where large clearances must be maintained between the electrodes to prevent electrical breakdown of the surrounding air, fixed and moving elements may be sectors of coaxial cylinders, or the combination of a fixed flat disk and a moving cylindrical sector. Damping may be either by means of a vane attached to the moving element, moving with small clearance in a closed sector box, or by means of a disk which moves in the field of a permanent magnet.

Energy storage in the electric field of the voltmeter is proportional to the square of the voltage between its electrodes, and the response of the voltmeter is to the r.m.s. value of the impressed voltage. Operating torque is always small in electrostatic instruments, and may be increased only within rather narrow limits by increasing the capacitance between the fixed and moving electrodes. If either the number of plates or their area is increased, the weight of the moving system will be greater, with a consequent increase in bearing friction. If capacitance is increased by decreasing electrode separation, a limit is reached in low-voltage instruments at the mechanical clearance required for reliable operation, and at high voltages by the clearance needed to avoid corona or electrical breakdown.

Electrostatic voltmeters have a response that is independent of frequency and indeed, if they are suitably constructed and operated, they have no differences in indication on direct or alternating voltage. Thus, they can serve as transfer instruments to determine the difference between A.C. and D.C. response of other types of instruments. In fact, the National Physical laboratory of Great Britain employs electrostatic instruments as their basic transfer standards in the same way that the national bureau of standards of the United States uses electrodynamic instruments.

7. Instrument Transformers.—Ratio devices in the form of transformers are needed to extend the range of alternating current instruments, so that current, voltage, power and energy can be measured with instruments of moderate size and capacity. This

is important in the laboratory, and of even greater importance in commercial metering. Here power is frequently handled in large blocks at high currents and voltages, and it is necessary that the devices used to measure large currents or high voltages be both accurate and of low power consumption. The requirement of low power consumption precludes the use of shunts for current measurements beyond a few amperes and of series resistors in voltage circuits beyond a few hundred volts.

A transformer consists of two coils of wire, closely coupled by means of a magnetic circuit of high permeability which threads through both coils. It is the property of such an arrangement that when one coil (the primary) is excited by an alternating current, an alternating voltage of the same frequency is induced in the other coil (the secondary). If the secondary circuit is completed by an external impedance that is very large compared with the impedance of the transformer winding, the ratio of the voltages at the primary and secondary terminals of the transformer is very nearly the same as the ratio of turns in the primary and secondary windings. This is an elementary picture of a voltage transformer.

On the other hand, if the secondary circuit of the transformer is completed by an impedance that is very small, the ratio of currents in the primary and secondary circuits is very nearly equal to the reciprocal of the primary-secondary turn ratio, and one has a current transformer.

Thus, the two basic types of instrument transformers (for voltage or current transformation) are similar in that each consists of a primary and secondary coil closely linked by a high-permeability magnetic core. They differ in details of construction and in the conditions under which they operate. A voltage transformer, used to step voltages down from high to low values, may have many times as many turns in its primary as in its secondary winding. It supplies a very small operating current to the high-impedance voltage circuits of the instruments connected across its secondary winding, at a voltage which is a known fraction of the voltage across its primary winding. A current transformer, used to step currents down from high to low values, may have many times as many turns in its secondary as in its primary winding; in fact, the primary winding is often either a single turn or even the high-current conductor passed through the central window of the magnetic core. It supplies the low-impedance current elements of instruments or meters connected across its secondary winding with a current which is a known fraction of the current in its primary winding.

Voltage transformers are usually designed with a 120-v. secondary, and current transformers with a 5-amp. secondary. Primary voltages may be 200,000 v. or more in some instances, and the rated primary current of current transformers sometimes ranges as high as 12,000 amp. Both by refinement of design and by the use of high-quality magnetic core materials, the modern instrument transformer produces a current or voltage for the instruments connected across its secondary terminals that is within a few hundredths of 1% of the intended value, and consumes very little power in its operation. Good instrument transformers reflect accurately, on a known reduced scale, the current or voltage of their primary circuits, and thus serve to broaden enormously the range of A.C. values that can be measured with relatively simple instruments.

B. Power Measurements

The power at any instant in an electric circuit is the product of that current in the circuit and the voltage across its terminals at that instant, and is a measure of the rate at which energy is being transformed or made available. For direct current under steady-state conditions, power can be calculated from a measurement of any two of three quantities—current I, voltage E, resistance R—by using the appropriate one of the following relations

$$\text{Power} = EI = I^2R = E^2/R$$

In the case of an alternating current the instantaneous power varies continuously as the current and voltage go through a cycle of values.

If the current and voltage are both sinusoidal, the time average of power, which is usually the quantity of interest, is given by the expression

$$\text{Power} = EI \cos \phi$$

where E and I are the r.m.s. or effective values of voltage and current respectively, and ϕ is the electrical angle between them. Cos ϕ is the power factor and may assume any value between unity and zero as the phase angle between voltage and current varies from 0° to 90°.

1. Electrodynamic Wattmeter.—This instrument, of similar mechanical construction to the electrodynamic instruments already described, is well suited to the measurement of A.C. power at low frequencies. The field coils of the instrument are connected in series in the circuit so that their current is that of the load being measured, and the moving coil (with appropriate resistance) is connected across the load so that its current is proportional to the load voltage. Then the instantaneous torque from the reaction of the field-coil current with the moving-coil current is proportional to the product of the current and voltage in the circuit, and hence to the instantaneous power. As the variations of instantaneous power are too rapid for the moving system to follow, the equilibrium position it takes up will correspond to the average torque and therefore to average power. The instrument scale is marked in watts. The voltage and current elements are brought out to separate terminals so that they may be connected properly to the load circuit.

For small or moderate currents (up to 5 or 10 amp.) the load current is sent directly through the field coils of the wattmeter. For voltages up to perhaps 300 v., the moving-coil circuit, including a series resistor to limit its current to 25 ma. or less, is connected directly across the load. When power measurements involve larger values of current or voltage, instrument transformers of appropriate ratios are used to step down at the instrument to values that can be applied to a wattmeter having a 5-amp. current range and 150-v. voltage range.

The use of electrodynamic wattmeters for power measurements is restricted to low frequencies, a few hundred cycles per second at most, because of eddy currents and self-inductance of the moving-coil circuit, both of which tend to alter the phase relation between the magnetic fields of the current and voltage elements of the wattmeter, and give rise to errors of indication that increase with increasing frequency. These frequency errors can be made negligibly small at commercial-power frequencies by suitable design and construction, and the electrodynamic wattmeter is much used as a transfer instrument for the calibration of other A.C. instruments in terms of D.C. measurements of current and voltage. Such D.C. measurements can be referred readily to the basic electrical standards of resistance and e.m.f. by means of a laboratory potentiometer.

2. Electrostatic Wattmeter.—The electrostatic wattmeter is substantially free from eddy-current and inductance effects, and can be constructed to be independent of frequency over a much broader range than can the electrodynamic instrument. Hence, it also is used as a basic transfer instrument by several of the national standards laboratories. However the available torque is quite small, as with all other electrostatic instruments. Because its construction is inherently delicate and the techniques of operation require great care and skill, the electrostatic wattmeter is almost never used in routine power measurements. The instrument torque results from the electric field between fixed and moving electrodes, but the electrode arrangement is more elaborate than in the electrostatic voltmeter.

There are two sets of stationary electrodes maintained at a potential difference proportional to the load current. This potential difference is provided by the voltage drop across a resistor that carries the load current. The voltage drop across the load is impressed between the moving element and the midpoint of this shunt (*i.e.*, at the mean potential of the two stationary electrodes). The instantaneous torque is proportional to the product of load voltage and load current at any instant, and the deflection of the moving element is proportional to the average power into the load.

3. Bolometer.—The wattmeters described above are designed to measure power into a load, and are applicable only at low fre-

quencies. The accurate measurement of power into a load becomes more difficult with increasing frequency, and no simple or even adequate techniques are available for such measurements at radio or microwave frequencies. However, the power output of a generating circuit can be accurately measured at any frequency by absorbing the output and converting the electrical energy to heat. This can be done in the laboratory with a calorimeter in which the rate of heat production, measured by differential temperature rise, is a measure of the power output of the generator.

A more convenient means of measuring power output is with a bolometer bridge. A thermistor element, having a very large temperature coefficient of resistance, forms one arm of a Wheatstone bridge and is arranged to absorb energy from the generator. Its resistance change, as its temperature rises with the absorption of energy, becomes a measure of the power output of the generator. Such a device can be calibrated in terms of the product of the measured direct current and voltage required to produce the same resistance change in the thermistor.

C. Energy Measurements

The measurement of electrical energy is, from the viewpoint of economics, one of the most important of electrical measurements. Where electric power is generated or consumed, the commodity that is sold is energy, the time integral of power. The basic unit of power is the watt, and the corresponding unit of energy is the watt-second or joule.

More familiar units are the watt-hour (3,600 watt-seconds) and the kilowatt-hour (36×10^5 watt-seconds or 1,000 watt-hours). This latter unit, the kilowatt-hour, is the energy unit commonly used in billings for electrical service.

1. Commutator Watt-Hour Meter.—Developed by Elihu Thomson in 1889, this device is commonly used for metering D.C. energy. It is essentially a small motor provided with a magnetic brake and geared to a register or set of dials, whose count is proportional to the total number of revolutions. The gear train between the rotor shaft and the register dials is of such a ratio that the dials read directly in kilowatt-hours. The motor field consists of a few turns of heavy copper wire carrying the current of the load being metered.

The armature (or rotor) current is proportional to the line voltage. In this respect the instrument resembles the electrodynamic wattmeter, and its driving torque is proportional to the product of load current and line voltage. The armature has a silver commutator and silver- or gold-tipped brushes; it is carried on jewel bearings to minimize friction. For proper operation it is essential that the rotor speed be proportional to driving torque (and to the power being metered), and this is assured by providing a retarding or braking torque of sufficient magnitude to keep the speed of rotation rather low.

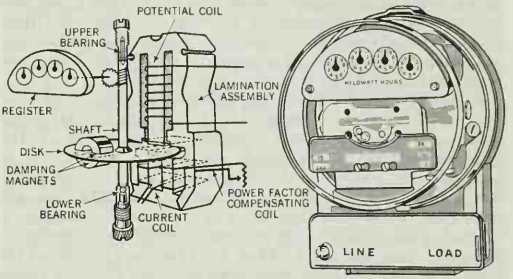
An aluminum disk is attached to the motor shaft and intercepts the flux of a permanent magnet. As the disk rotates, eddy currents are induced in it by the flux that it cuts, and the counter torque which results from the reaction between these eddy currents and the field of the magnet is proportional to the disk speed. Therefore, the speed of rotation of the motor shaft is proportional to the load power, and its total number of revolutions over a time interval is proportional to the energy consumed by the load during the interval.

2. Induction Watt-Hour Meter.—The induction watt-hour meter is used almost universally for metering A.C. energy. Its principle of operation, identical with that of the induction motor, may be understood by considering two laminated electromagnets A and B, situated on either side of an aluminum disk and displaced slightly from one another along its periphery. The alternating magnetic field of A induces eddy currents in the disk that intercept the field of electromagnet B, producing a torque on the disk. Conversely eddy currents induced in the disk by electromagnet B intercept the field of magnet A, and react to produce a torque. If the magnetic field of B lags in phase behind the field of A, the two torques are in the same direction and their sum is proportional to the product of the currents producing the fields and to the sine of their angular phase difference.

To produce a torque in the rotating disk proportional to load power, one of the electromagnets (say A) is wound with a few turns of heavy wire and is connected to carry the load current. The other electromagnet (B) is wound with many turns of fine wire and is connected between the power lines so that its current is proportional to load voltage. This electromagnet is designed to have a very large inductance and the current in its coil lags almost 90° behind the voltage producing it. By using an additional shading coil, the flux of this magnet intercepted by the disk, is made to lag precisely 90° behind the voltage and, since the sine of 90° is unity, maximum torque is developed if the current in the series coil (electromagnet A) is in phase with the voltage, *i.e.*, for a unity power-factor load. As in the commutator meter, the aluminum disk passes between the poles of a permanent magnet to provide a braking torque proportional to speed.

A gear train drives a register whose count is proportional to total revolutions of the shaft, and thus to energy consumption, providing a basis for billing the power customer.

Fig. 3 shows a single-phase meter such as is employed to meter the energy used in the ordinary household. Other meter types have two driving elements for a three-wire distribution system, or three elements for a four-wire system. For very large currents,



BY COURTESY OF SANGAMO ELECTRIC CO.

FIG. 3.—SINGLE-PHASE WATT-HOUR METER: (LEFT) SCHEMATIC; (RIGHT) ASSEMBLED

where huge blocks of power are metered for an industrial customer, the current coils of the watt-hour meter are connected through current transformers. When the metering must be done at high voltages, voltage transformers are also used to connect the meter to the power lines.

Because of the very large number of meters in use, and the high total value of the electrical energy consumed annually, a great deal of engineering talent has been devoted to refining watt-hour meter design. A modern meter may be expected to have an accuracy of nearly 1% over a wide range of loads and at temperatures ranging between the extremes of winter and summer, and to retain this accuracy over a period of many years with little or no maintenance.

D. Resistance Measurements

Depending on the accuracy required, it is possible to measure a resistance with a deflecting instrument called an ohmmeter, or compare its value with that of a known resistance in a ratio network such as the Wheatstone bridge.

Deflection methods generally may be expected to yield an accuracy of a few per cent, whereas bridge methods may be used with ordinary precautions for work which requires values to 0.1% and, with care, to 0.01% or better. In the national standardizing laboratories and in other laboratories having comparable equipment, nominally equal resistances can be compared in a bridge network to 1 part in 10,000,000.

1. Ohmmeter.—Ohmmeters are of two types. The series ohmmeter, which forms a part of many inexpensive multipurpose testing instruments, consists of a D.C. milliammeter in series with a small dry-cell battery and an adjustable rheostat. A gap in this circuit is provided with binding posts or test leads so that the resistance to be measured can be inserted conveniently into the circuit. With the test gap shorted out, the milliammeter is set by

means of the rheostat to a reference point on its scale marked zero. The pointer position with the gap open, so that there is no current in the circuit, is marked infinity.

When a resistor is connected across the gap to complete the circuit, the instrument pointer assumes a position intermediate between the zero and infinity marks, and the scale is marked in terms of resistance.

The ratio (or crossed-coil) ohmmeter represents a substantial improvement, as its reading is nearly independent of supply voltage and it need not be set to a reference mark each time it is used. It is a permanent magnet instrument with two moving-coil systems arranged so that their torques oppose one another. The circuit, containing a voltage source, is so arranged that the current in one coil is proportional to the voltage across the resistor to be measured. The current through the other moving coil goes also through the resistor. Thus the torques resulting from the currents in the two moving coils represent respectively the voltage across the resistor and the current through it. As these torques oppose one another, the instrument pointer takes up a position representing their ratio, the quotient of the voltage by the current in the resistor.

The instrument scale is marked in resistance units. Such instruments, with a supply voltage ranging from 500 to 5,000 v., are used for measuring the resistance of electrical insulation, and their scales are usually marked in megohms. A somewhat similar type of crossed-coil instrument is arranged for four-terminal measurements, and its scale may be marked in microhms.

2. Wheatstone Bridge.—The Wheatstone bridge consists of two parallel branches (as shown in fig. 4), carrying currents i_1 and i_2 respectively, supplied from a common voltage source. If the individual resistors of one branch, say p and r, have a ratio of fixed value, the resistors in the other branch can be brought to the same ratio by adjusting the value of one of them. The ratios are equal when the potential drop caused by the current i_1 in resistor p is equal to the potential drop resulting from i_2 in q. Simultaneously, of course, $i_1 r = i_2 s$. Thus, when the resistance ratios are equal in the two branches, there is no potential difference across the galvanometer; and its zero indication demonstrates balance in the bridge. For this condition $p/r = q/s$ or $q = s \times p/r$. The value of the resistor q is determined from a known ratio p/r and a known resistance s. At balance it is also true that $p/q = r/s$ and it follows that the galvanometer can be interchanged with the voltage source in the network without affecting the balance condition.

This interchangeability is, in fact, characteristic of any bridge network, and can frequently be used to advantage, by placing the voltage source and the detector of unbalance to obtain best sensitivity; *i.e.*, larger detector response to a given proportional unbalance of the bridge and, hence an observable response to a smaller unbalance.

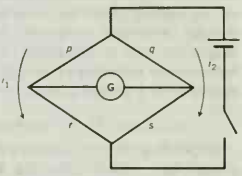


FIG. 4.—WHEATSTONE BRIDGE

If the voltage sensitivity of the galvanometer is known for the circuit resistance which it encounters in the bridge, its response to any specified proportional departure from the balance condition can be computed easily. The unbalance voltage e, acting to deflect the galvanometer, is given by the formula

$$e = E\Delta\frac{pr}{(p+r)^2} = E\Delta\frac{qs}{(q+s)^2}$$

where E is the supply voltage at the bridge terminals and Δ is the proportional unbalance. It should be noted that the alternative formulas provide for a departure of any arm from the balance condition; *i.e.*, the expression is used which includes the unbalanced arm.

The Wheatstone bridge is regularly used in a variety of forms for the precise measurement of resistance in the range from 1 ohm to 100 megohms. For a resistance less than an ohm, the resistance introduced at the terminals of the bridge when connecting it into a circuit becomes increasingly important with decreasing total resistance. For example, if the terminal resistance amount to 0.001 ohm and the resistor itself is 0.01 ohm, the terminals contribute 10% of the whole. Hence, the precise definition and measurement of low resistances must avoid inclusion of these terminal resistances.

Low-valued resistors in the precision class have four rather than two terminals, the current being introduced through one pair and the potential drop measured between the other pair. The resistance of a four-terminal resistor is defined as the ratio of the voltage difference between the potential terminals to the current entering and leaving the current terminals. Bridges for measuring or comparing four-terminal resistors must have two pairs of ratio arms rather than one. The Kelvin bridge network shown in fig. 5 is such an arrangement.

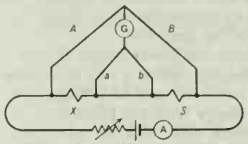

FIG. 5.—KELVIN BRIDGE

E. Capacitance and Inductance Measurements

Alternating current networks similar to the Wheatstone bridge are used to measure capacitance or inductance. One of the network branches may form a ratio pair and the other branch may be used to compare one inductor with another, or one capacitor with another. The value of the unknown element is determined from a known standard of the same kind, and the known ratio. The ratio arms of the bridge may be made up of two resistances, two inductances or two capacitances.

In any A.C. bridge, balance is possible only when there is no potential difference across the detector at every instant throughout the A.C. cycle. Thus, the ratio arms should have the same time constants, and the elements being compared should have equal phase angles. In other words, both magnitude and phase-angle balances are required in an A.C. bridge. This usually means that a resistance must be inserted in the arm containing one or the other of the elements being compared, to bring their phase angles to equality.

The Wheatstone network can also be arranged in a form known as the product-arm bridge, in contrast to the ratio-arm network just described. In this arrangement a capacitor can be compared to an inductor in the opposite arm, the remaining opposite pair of arms being resistors. Thus a capacitance can be measured in terms of an inductance and the product of two resistances, or an inductance can be measured in terms of a capacitance and a product of resistances.

To summarize the possibilities, if two capacitors (or two inductors) are to be compared in a four-arm bridge, they must be in adjacent arms. If a capacitor is to be compared with an inductor, they must be in opposite arms.

V. RECORDING INSTRUMENTS

In industrial and laboratory operations it is often necessary to have a record of the variations of voltage, current, power or some related quantity over an extended time interval. To make such a record, moving a pen over a paper chart, requires much more power in the operating mechanism of the instrument than is needed merely to indicate with a pointer the value of an electrical quantity. Direct-writing recorders have moving systems similar to those of the corresponding indicating instruments except that the torque requirements may be a hundred or even a thousand times greater. Some kind of clock mechanism must be incorporated into the instrument to move the chart paper at a uniform rate.

A second type, called a servo-recorder, has a small motor which takes its power from an auxiliary source and moves the pen across the paper. Servo-recorders make use of either a bridge or a potentiometer network in which a quantity is measured in terms of the balance position of a slide-wire that forms part of the network. When the network is unbalanced, the output of a detector or sensing element is fed into an amplifier. The amplifier output is applied to the motor which drives the slide-wire and the recording pen in the proper direction to restore balance to the network.

Large numbers of servo-recorders are used in industrial plants to record temperatures of furnaces or stills, using a thermocouple or resistance thermometer, or to record, by means of an electrical weighing device, the rate of flow of a material used or produced. In short, servo-recorders can be used to make a continuous record of any quantity which can, by some type of transducer be made to produce an electrical signal.

Frequently the amplifier output from the unbalance signal, or the position of the recording pen, is used to initiate controlling devices so that the entire operation is automatic except for supervision.

INSUBRES, a Celtic people of upper Italy, the most powerful in Gallia Transpadana. Their origin is obscure. Livy, whose account (v, 34) is not reliable, regards them as Aedui who came into Italy over the Montgenèvre pass. By about 400 B.C. the Insubres controlled a large area around their capital city, Mediolanum (Milan). From 225 to 194 B.C. they were frequently at war with the Romans; they helped Hannibal in the Second Punic War. In 222 B.C. they were defeated at Clastidium (mod. Casteggio) by M. Claudius Marcellus, who gained the *spolia opima* by slaying with his own hand their king Viridomarus; and in 194 B.C. they were finally subdued by L. Valerius Flaccus. Thereafter their tribal identity was gradually lost in the rise of municipal communities. The area was given Latin rights in 89 B.C. and full Roman citizenship in 49 B.C. *See* Gaul, Cisalpine.

INSULATING MATERIAL (ELECTRICAL). Electrical insulation is nonconducting material used to hold electrical conductors in position, separating them from each other and from surrounding structures. Insulation forms a barrier between energized parts of an electric circuit and confines the flow of electric current to wires or other conducting paths as desired. The insulation of electric circuits is a necessary requirement for the successful operation of all electrical apparatus.

Various types of materials are used as insulation, the selection being made on the basis of the specific requirements of each application. The copper conductors used in the electrical wiring in homes are insulated from each other and from the building by rubber or by plastics. These materials are low in cost, long lived and sufficiently flexible to withstand necessary bending. Extension cords of heating appliances are usually insulated with asbestos, a material which is capable of withstanding high temperature without deterioration. Overhead power lines operating at high voltage are supported on porcelain insulators which are unaffected by outdoor exposure. Paper is used to insulate the small wires of telephone cables and the conductors of high-voltage power cables; in the latter case the paper is impregnated with insulating oil to improve the quality of the insulation. Large electric generators and motors which operate at high voltages and high temperatures are insulated with mica. In some applications, solid insulation is used in conjunction with liquid or gaseous insulation. For example, in high-voltage transformers, solid insulation provides mechanical rigidity while insulating oil contributes to increased insulation strength and serves to carry heat out of the structure.

Electrical insulation is ordinarily regarded as a nonconducting material, but is, in fact, better described as a poor conductor or a substance of high resistance to the flow of electric current. Different insulating and conducting materials are compared with one another in this regard by means of a material constant known as the resistivity, the resistance measured across identically dimensioned samples of the several materials. The resistivities of a number of insulating materials are shown in the following table, along with the resistivity of copper, the most commonly used conductor material. As may be seen, the resistivities of the insulating materials are vastly greater than the resistivities of the metal. Nevertheless, in the normal operation of electrical equipment, minute conduction currents flow through the insulation separating the energized parts and a small amount of heat is thereby released within the insulation.

Under the influence of ordinary voltage application, insulation has extremely high resistance to current flow. However, if the voltage gradient (volts per centimetre thickness of insulation) exceeds a critical value, the resulting rearrangement of the atomic structure of the material results in a sudden decrease in the resistance of the material to such an extent that high-value currents may flow through local regions. Such a change leads to breakdown or "puncture." In the case of solid insulation, puncture represents permanent damage to the material, whereas in the case of liquid or gaseous insulation, the interruption of the current flow and the removal of the offending overvoltage restores the material to substantially original conditions. The puncture strength of several insulating materials is shown in the table.

Characteristics of Insulating Materials

Material	Resistivity ohm-cm.	Puncture strength volts per cm.	Relative permittivity
Air (20° C., 760 mm. Hg)	Very high	3×10^{4}	1.0
Amber	5×10^{18}		2.9
Bakelite			4.5–5.5
Glass	2×10^{13}	$0.5–3.0\times10^{6}$	5.4–9.9
Mica	2×10^{17}	$3.5–7.0\times10^{6}$	2.5–6.6
Oil	1×10^{12}	1.0×10^{5}	2.2–4.7
Paper		$1.0–4.0\times10^{6}$	2.0–2.6
Porcelain	3×10^{14}	1.0×10^{5}	5.7–6.8
Quartz	5×10^{18}	$2.0–2.5\times10^{5}$	3.5
Rubber	1×10^{15}		2.0–3.5
Copper	1.6×10^{-6}	...	...

Data from *Standard Handbook for Electrical Engineers*, 8th ed. (McGraw-Hill Book Company, Inc., New York, London, 1949). Electrical properties may vary considerably, depending on the processes of material preparation and the methods of test.

Two conducting bodies separated by insulation form a capacitor which is said to possess capacitance, the ability of the assembly to store an electric charge while voltage is being applied. The capacitance is influenced by the relative permittivity of the material employed as insulation. The relative permittivity of a material is defined as the ratio of the two capacitance values: (1) the capacitance between the two electrodes separated by the insulating material; and (2) the capacitance between the same electrodes with a vacuum replacing the subject material. The relative permittivities of several insulating materials are shown in the table.

The insulation material separating two electrodes is stressed when normal voltage is applied to the electrodes and this stress is reversed with each reversal of the applied voltage. This change of stress involves molecular rearrangement within the insulation with the attendant release of a small amount of heat with each reversal. If the applied voltage is of low frequency (such as 60 cycles per second), this release of heat is ordinarily of little concern. At the high frequencies employed in many communications systems (millions of cycles per second), this heat release may be evident by insulation temperature rise and by a loss of energy from the electric circuit. Special plastics, ceramics and glasses, exhibiting very low heat loss at high frequency, have been developed for the communications industry.

Insulating materials are subject to many deteriorating influences, the most important of which are moisture absorption and chemical changes. Porous materials, such as cotton and paper, must be effectively sealed against moisture, usually by immersion in oil or by impregnation with insulating varnishes. Silicone varnishes are used extensively as they form a very effective barrier against moisture and can withstand fairly high temperatures.

Insulating materials deteriorate under influences which change their chemical structures. Chemical changes which progress very slowly at room temperatures are, in some cases, greatly accelerated at elevated temperatures. For this reason, many types of electrical apparatus have specified maximum operating temperatures.

If operated at higher temperatures, insulation life will be noticeably shortened. Some organic compounds are damaged by exposure to ultraviolet light and corona, a product of high-voltage stress in air.

See ELECTRIC POWER: *Transmission; see* also references under "Insulating Material (Electrical)" in the Index. (J. R. E.)

INSULATING MATERIAL (THERMAL). The advantages of heat insulation must have been known very early in history. The comforts of fur clothing and snowhouses of the Eskimo, for example, certainly were realized hundreds of years ago. Wood was used for insulating steam boilers, engine cylinders and pipes early in the 19th century. The extensive development of commercial insulation, however, did not begin until about 1900.

Purposes of Heat Insulation.—The chief use of insulation is to retard the rate of heat flow. This may reduce the heat flow outward from a building or furnace, for example, or inward to a cold-storage warehouse. Great savings in fuel and electricity are made possible by the proper installation of insulation and it is often used to prevent condensation of water vapour on the inside of factory roofs where the manufacturing process requires or develops a high relative humidity, as in cotton or paper mills. Cold-water pipes in buildings are frequently insulated solely to prevent condensation and consequent dripping on warm humid days.

Working and living conditions can often be made more comfortable by the use of insulation. Buildings can be made cooler in summer and the working conditions around furnaces, hot flues, etc., improved. The addition of insulation to buildings, bake ovens, furnaces, etc., tends to produce a more uniform temperature distribution.

The low heat capacity of insulating firebrick is an important factor in saving fuel used by intermittently heated furnaces. The time required to reach a desired temperature may be reduced by the use of lightweight insulating firebrick to one-quarter that needed when conventional heavy firebrick is used.

Insulation is sometimes applied to structural steel in buildings to reduce the fire hazard. Underwriters' tests indicated that unprotected structural steel collapses quickly in a hot fire. The thermal expansion of concrete roof slabs can be much reduced by the use of insulation.

Proper insulation also will minimize the formation of lath patterns on walls of plaster over wood lath.

Factors Affecting the Value of Insulation.—The coefficient of thermal conductivity or K value of insulating materials increases with an increase of temperature. The loose fibre type generally increases much faster than the more solid type such as corkboard or 85% magnesia, as shown below:

Glass wool	2.1 lb./cu.ft.	0.28 @ 100° F.	0.55 @ 300° F.
85% magnesia	12 lb./cu.ft.	0.38 @ 100° F.	0.43 @ 300° F.

When referring to a K value of an insulating material, it is important to note the corresponding temperature. For insulating materials used at temperatures below 70° F. (21.1° C.), provision should be made to prevent moisture from entering the insulation. This is necessary because water has a K value more than ten times that of most insulating materials, and if it is present in the insulation the effective K value is increased materially and usually other difficulties develop. In cold-storage plants as well as houses, water vapour tends to enter from the warmer side and condense in the cooler parts of the insulation. Thus every effort should be made to seal the warmer sides of such walls so that they will be impervious to water vapour. This problem becomes especially serious when extremely low temperatures are encountered.

In general, for any given insulating material, the K value will increase with density but there are notable exceptions in the case of many loose fibrous materials and some powders. Bagasse (sugar cane fibre) has a minimum K value at a density of four pounds per cubic foot, the K value increasing if the density is made greater or less than this amount. Another factor that tends to increase the K value of a few insulating materials is radiation through the material and, in special cases of loose fibrous materials, there may be convection currents of air transmitting heat from the warm side to the cool side.

Types of Insulation.—Heat insulating materials may be roughly classified as follows: (1) powders, such as diatomaceous earth, silica aerogel, sawdust, etc.; (2) loose fibrous materials similar to eelgrass, glass wool, rock wool, shredded redwood bark, etc.; (3) blanket insulation, consisting of glass wool, rock wool, wood fibres, etc., enclosed by paper, cloth or wire mesh; (4) board or block insulation, such as corkboard, fibreboard, expanded glass block, 85% magnesia, vermiculite block, etc.; (5) insulating refractories such as diatomaceous earth and kaolin bricks; (6) heavy refractories such as fire clay, magnesite, silica bricks, etc.; (7) reflective insulation, consisting usually of aluminum foil with an adjoining air space. Reflective insulation is effective because it reflects a high percentage of the radiation striking it and also emits a small percentage of the amount of heat radiated by ordinary (nonmetallic) surfaces under the same temperature conditions.

See HEATING AND VENTILATION; *see* also references under "Insulating Material (Thermal)" in the Index. (G. B. Ws.)

INSULIN is a hormone secreted into the blood by cells situated in the pancreas; its chief function is to regulate sugar metabolism. Insulin, extracted from the pancreas of certain domestic animals, is administered to persons suffering from diabetes mellitus, in whom there is an absolute or relative deficiency of insulin. It is also used to some extent in the treatment of mental disease.

In mammals, in which the pancreas is well defined, the insulin-secreting cells lie in scattered groups called the isles of Langerhans, distributed among the relatively much larger groups, or acini, of pancreas cells. In certain fishes in which the pancreas does not occur as a definite gland but is spread out diffusely in the mesentery, the islet cells form compact encapsulated glands called the principal islets, which are often of considerable size and contain no pancreatic (acinar) cells.

In 1889 J. von Mering and Oskar Minkowski found that complete extirpation of the pancreas in dogs immediately caused severe diabetes, and it was not long before the hypothesis was formulated that this must be due to the withdrawal from the body of a hormone having the function of regulating the metabolism of the carbohydrates.

The name insulin was first suggested for a hypothetical internal secretion of the pancreas by J. de Meyer in 1909. Many attempts were made to extract it from the pancreas, but with little success. In 1921, however, Sir Frederick Banting and Charles H. Best, working in the laboratory of J. J. R. Macleod, found that extracts of partially degenerated pancreas and later of normal pancreas contained the hormone.

These observations demonstrated that insulin does exist in the pancreas, and the next step was to devise a method for extracting it in more purified form and in quantity from normal pancreas. Alcohol was found to be a suitable extractive, in that it dissolved the insulin and at the same time eliminated undesirable contaminants. Crude insulin prepared in this way by Banting and Best was first administered to human patients in Jan. 1922. Later J. B. Collip succeeded in sufficiently purifying the alcoholic extracts, by a process of fractional precipitation, so that they could be injected subcutaneously in man without causing local irritation. Very potent extracts were also prepared from the principal islets of fishes. Further purification of the extracts was effected by precipitating the insulin, either by adjustment of the reaction (isoelectric precipitation) or by means of picric acid followed by treatment with alcoholic hydrochloric acid (insulin hydrochloride).

The structure of the insulin molecule was elucidated theoretically in 1955 by Frederick Sanger (*q.v.*) of Cambridge university. Artificial synthesis of insulin (the first such synthesis of a naturally occurring protein) was achieved in 1964 by P. G. Katsoyannis and colleagues at the University of Pittsburgh.

The function of insulin is to promote the formation and storage of glycogen (a complex sugar), of fat and of protein; it increases the burning of sugar and decreases its excessive new formation from protein; it helps in the regulation of potassium and phosphate metabolism. Insulin counteracts the inhibitory effects of several other hormones on these processes.

When insulin is absent from the blood, as after surgical removal of the pancreas or when the islets are destroyed by disease (diabetes), less sugar is used and sugar production takes place in the liver more rapidly. The blood sugar becomes very high (hyperglycemia) and sugar appears in the urine (glycosuria). At a later stage substances known as ketone bodies also appear in the blood and urine (ketonuria), being derived from the incomplete oxidation chiefly of fatty acid but partly also of certain of the amino acids. Death ultimately occurs, either because of starvation caused by the excessive using up of the available foodstuffs of the body, or because of toxic effects for which the ketone bodies are believed to be largely responsible (diabetic coma). Insulin promptly removes all these symptoms when injected under the skin or into a blood vessel; it is inactive when given by mouth, because it is destroyed by the digestive ferments of the intestine. The effect passes off in a few hours, so that the injections must be repeated at least twice daily unless some material is combined with the insulin to slow the rate of its absorption. There are available various forms of slow-acting insulin.

When insulin is injected into normal animals the blood sugar, which usually stands at about 0.10%, rapidly diminishes; when it reaches a level at between 0.04% and 0.05%, curious symptoms supervene.

In most of the laboratory animals these hypoglycemic symptoms consist at first of nervous overexcitability leading to convulsions, and later of coma and fall of temperature. That the symptoms are related to the disappearance of free glucose from the blood is indicated by the fact that they are promptly removed by restoring glucose to the blood, either by giving sugar by mouth or by injecting solutions of glucose. Glucose is conspicuously more efficient as an antidote than any other sugar, even than mannose and laevulose which are so closely related to it chemically. The mechanism by which excess of insulin causes hypoglycemia in the normal animal is an exaggeration of its usual action; *i.e.,* it increases the burning of sugar and its storage as glycogen and fat.

There are no true substitutes for insulin, though a great variety of oral hypoglycemic agents have been tested. Some of these are related to guanidine (*q.v.*) and have produced liver injury. A series of compounds resembling the sulfonamides in chemical structure also have been tested in animals and man. One of these, called tolbutamide, produces very little toxicity in human subjects and gives very promising results in certain older mild cases of diabetes. Since tolbutamide, unlike insulin, is a substance foreign to the body, careful watch must be kept for many years to make certain that no ill effects appear. Some insulin, either natural or administered, must be available in the body for the hypoglycemic effects of tolbutamide or related drugs to be exerted. This agent is not effective in childhood diabetes or in the adult diabetic who is in acidosis or coma.

Since insulin can be prepared in crystalline form (J. J. Abel and E. M. K. Geiling) it may be weighed out for medicinal use, but it is more convenient to use it in liquid form, which keeps well in acid reaction. The strength of the liquid in actual insulin is determined by biological methods, one of which depends on the lowering of blood sugar in a normal rabbit. The strength is gauged in units, one unit of insulin being originally defined as the amount that on subcutaneous injection will lower the percentage of blood sugar to the convulsive level, 0.045%, for a period of five hours in a fasting rabbit of two-kilogram weight. In order to ensure uniformity in the strength of insulin manufactured in different countries, the health committee of the League of Nations set up a sufficient quantity of dried insulin. Later this original "yardstick" was replaced by purer, more potent standard preparations.

Testing laboratories maintain their own standards but they can have them checked against the international standard from time to time. By such international uniformity in strength of insulin, the diabetic patient is insured against variable dosage.

See also Animal Extracts; Diabetes Mellitus; Hormones, Vertebrate; Pancreas; and references under "Insulin" in the Index. (J. J. R. Macl.; C. H. B.)

INSULL, SAMUEL (1859–1938), U.S. public utilities executive known for his contributions to good utility operations and his mistakes in utility financing, was born in London, Eng., Nov. 11, 1859. He studied bookkeeping, worked with one of Thomas A. Edison's representatives and in 1881 went to the United States to become Edison's private secretary. When the Edison General Electric Co. was formed in 1889, Insull became a vice-president in its main office at Schenectady, N.Y. In 1892 he became president of the Chicago Edison Co., and four years later became a U.S. citizen. By 1907 the entire business of supplying electricity to the city of Chicago was in the hands of Insull's organization, now named the Commonwealth Edison Co. As a utilities executive he advocated the practice of supplying many communities from a central electrical station, and by 1917 his systems covered most of Illinois and extended into neighbouring states. He formed his first holding company, Middle West Utilities, in 1912.

During the 1920s Insull's electrical systems grew phenomenally, based in part on the use of central stations and in part on the formation of holding companies. Insull also promoted the sale of electrical utility stock to a great number of investors during the speculative era of the 1920s. With the depression of the early 1930s, his ambitious holding company pyramid collapsed, and in 1932 he fled to Europe, where he waged a losing battle to escape extradition. He was returned to Chicago in 1934 and was tried three times on charges of fraud, violation of federal bankruptcy laws and embezzlement, but was acquitted each time. He died on July 16, 1938, in Paris.

See Francis X. Busch, *Guilty or Not Guilty* (1952); F. McDonald, *Insull* (1962). (J. R. Lt.)

INSURANCE. Insurance may be described as a social device whereby a large group of individuals, through a system of equitable contributions, may reduce or eliminate certain measurable risks of economic loss common to all members of the group. Its primary function is to substitute certainty for uncertainty as regards the economic cost resulting from the accidental occurrence of disastrous events. Its effect is to spread the cost, which normally would fall upon a single individual, in an equitable manner over the members of a large group exposed to the same hazard.

Throughout the history of the institution there has been a tendency to restrict the word "assurance" to life business, although in England during the 18th century the word was also applied to other classes of business, *i.e.,* fire and marine. Even today in England, lawyers use the word "assured" to describe any person insured. An attempt has been made in the past to distinguish between "assurance" and "insurance" on the basis that the former relates to the insurance against a contingency which must happen (as for example in life business, where a person must either die or attain a certain age), while insurance is supposed to relate to all other contingencies (which can be insured against, but may not occur, as in the case of fire or burglary). The point is largely academic, but in England, life business is usually referred to as "assurance" and other classes as "insurance." From the beginning the term "insurance" seemed to find greater favour in the U.S.

Risk and Insurance.—Not all risks are insurable, nor is insurance the sole method of dealing with economic risk. Risk itself is the result of hazard. Risk is the chance of loss; hazard, the source of the loss. Hazards may be classified as physical or moral, or as those affecting all members of a community alike, such as business cycles and earthquakes, and those affecting only particular individuals, such as fire and theft. Risks based on a moral hazard are not regarded as insurable. Many of those affecting all mem-

bers of a community alike, such as unemployment arising out of the business cycle, are insurable only by the device of social insurance to be discussed later.

For insurance purposes it is important to distinguish the two broad classifications of risk, namely (1) pure risk and (2) business or speculative risk. The first is unilateral and negative, involving only the chance of loss. The second is bilateral, including the alternative possibilities of loss or gain. The latter is usually sought by those willing to incur the chance of loss as an appropriate price to pay for the prospect of a possible gain. Only pure risks are regarded as appropriate subjects for insurance. In addition, to be insurable, a risk must be measurable in quantitative terms, for which purpose the law of large numbers and the theories of probability and chance are employed. The law of large numbers is based on the observation that the larger the number of instances taken, the closer the result approaches the theoretical probability. Probability of loss may be expressed as a fraction, of which the denominator is the number of units exposed to loss and the numerator the number expected to be lost within a given period. Assuming adequate data on exposure and loss, probability of loss then becomes the ratio of losses to exposed units. To convert the probability of loss into "expectation of loss" or value of the risk, the probability of loss is multiplied by the average value of the units exposed to loss. Assuming, for example, the average value to be $10,000 and probability of loss 10/10,000, the expectation of loss will be 10/10,000 × $10,000 or $10.00. This amount may be called the pure premium or the individual loss-cost-share applicable to each unit in the group. Thus, if each unit in the group contributes this amount and experience conforms to the expectation, all losses will be covered.

In addition to the requirement that risks, to be insurable, must be of the pure variety as described above and must also lend themselves to measurement in quantitative terms, certain other conditions must be met before the institution of insurance may function. (1) The risk must be genuine, must exist for large groups of people, and its existence must be recognized by a sufficient number to warrant the establishment of an organization or organizations to insure it. (2) Persons exposed to the risk must feel a sense of responsibility for the possible loss and its consequences. (3) Those concerned must possess the resources with which to pay their pro rata share of the cost or the premiums. (4) The magnitude of the potential loss must be sufficient to cause a real hardship for the individuals upon whom actual losses may fall (magnitude, of course, is important only relatively to the resources of the individual). (5) The events concerned must be accidental, or fortuitous in character; they must occur according to the laws of chance and not be subject to control by those seeking to insure. Finally, (6) if a catastrophe hazard exists for a particular insurer, it must lend itself to effective control through appropriate risk-selection methods, reinsurance or other means.

Risks which ordinarily meet the requirements for insurance may be classified for convenience into two broad categories—risks to persons and risks to property. Those in the first group may be called personal risks, and the forms of insurance which may be applied are called personal insurance. Loss of income to the individual or his dependents may result from death, disability from accident or illness, unemployment or old age and may be insured against by life, health or unemployment insurance. Insurance applying to those in the second group is called property insurance. Loss may result from damage or destruction of specific property by fire, windstorm, hazards of the sea, earthquake, water leakage, explosion, riot and civil commotion, vandalism, theft, forgery, and, in the case of vehicles and their contents, collision. In addition, loss of property may result from the liability to pay compensation to injured employees under a workmen's compensation statute, or to pay damages because of injury to the persons or property of others, because of negligence in personal conduct or in the maintenance or operation of physical property. Although injury to a person may be the source of liability, insurance against this risk is normally provided by companies operating largely in the property insurance field. Similarly, business interruption or use and occupancy insurance also may be included in the property insurance category, for property insurers normally cover such risks, adapting direct-loss policy forms for the purpose.

Voluntary or Commercial Insurance.—The modern institution of insurance is divided into the two broad categories of voluntary or commercial insurance and compulsory or social insurance, both relying on the same basic principles but differing in many details of philosophy and organization. The description of insurance as set out above applies equally to both categories. A somewhat narrower definition may be employed, however, to describe those forms falling within the voluntary or commercial category. A widely cited definition was first enunciated in Great Britain in the case of *Lucena* v. *Crawford*, 2B & PNR 269 (H.L. 1806): "Insurance is a contract by which the one party, in consideration of a price paid to him adequate to the risk, becomes security to the other that he shall not suffer loss, damage, or prejudice by the happening of the perils specified to certain things which may be exposed to them." The document evidencing the transaction is known as a policy and the price paid is the premium. Those seeking insurance are required to have an insurable interest, *i.e.*, they must stand to lose by the happening of the event contemplated; otherwise the transaction would constitute merely a wager and would be unenforceable if not actually illegal. Where insurable interest exists, payment of a loss becomes an indemnity, not a gain as would be the case with a wager. Because such interests attach to persons, and because the character of the person is an important element of the risk, the insurance contract is spoken of as a personal contract and is not transferable without the agreement of all parties.

The business of voluntary or commercial insurance as usually conducted falls into four general divisions—life, fire, marine and casualty. In England the term "accident insurance" is applied to the branch of insurance for which the term "casualty" is used in United States practice. Marine insurance, which traces its origin back to the Italian traders of the 15th century or earlier, continues as a specialized branch of the business. Life assurance, known to have existed in England as early as 1583, did not at first merge with other forms to any great extent. By the 1950s, however, many of the life assurance companies had come to transact all classes of insurance business, either directly or through subsidiaries. The sale of annuities is usually coupled with that of life insurance.

Fire insurance, originating in its modern form following the Great Fire of London in 1666, continued for many years to be concerned with the fire hazard exclusively. Not until the 20th century were the hazards of wind, water damage, explosion and other so-called allied fire lines added extensively to the list of those insured by fire companies. The expansion of this branch of fire insurance company operation was particularly marked in the United States. Inland transportation hazards are also usually insured by fire insurance companies in the United States.

Personal accident insurance, which came into being about the middle of the 19th century, is a specialized branch of the business that has expanded to include the hazards of illness, hospital and surgical expense and related costs of illness and accident. Other special forms, such as steam boiler explosion, glass breakage, employer's liability, public liability, workmen's compensation, automobile insurance, as well as corporate bonding, are handled by specialized insurers or, in the U.S., by so-called casualty carriers.

Only after 1948 in the United States could a single company on a wide scale offer insurance of virtually all the forms mentioned above (except life insurance and annuities). This so-called multiple-line underwriting had long been practised in the rest of the world, but only in the second half of the 20th century was it permitted by the laws of all the states.

The extent to which property hazards are insured at different times and in different parts of the world tends to vary with the amount of property subject to loss and with general commercial and industrial development. While life insurance, which may be regarded as typical of the personal forms, depends upon the availability of income for its purchase, the extent to which income is so employed seems to depend more upon the customs and attitudes of the people.

Organization of Commercial Insurance.—The organization for the conduct of insurance on a commercial basis consists of four principal parts, as follows: (1) insurers, whose principal function is to assume and carry the risk; (2) a field organization, the principal function of which is to maintain contacts with the public for the writing of insurance and the settlement of losses; (3) intercompany organizations called associations or bureaus, with a variety of functions, including the establishment of standards, the making of rates, research, institutional advertising, dissemination of information, influencing legislation, and other activities designed to promote the interest of insurers; and (4) organizations of agents and brokers, called associations or boards, which, in the United States, perform many of the functions listed under (3) and are designed in general to promote the interests of agents and brokers.

Insurer organizations fall into two classes: those organized as private enterprises, including individual underwriters, syndicates of underwriters, and corporations or joint-stock companies organized on a capital stock basis; and those organized as co-operative enterprises, including mutual companies or associations, reciprocal or interinsurance exchanges, and a number of special types. Although important at one time, the practice of individual underwriting, so-called because of the practice of indicating acceptance of the risk by a signature written at the bottom of the policy, together with an indication of the fraction to be assumed, has largely disappeared, except as carried out through Lloyds of London. The capital stock form of organization is employed to provide all forms of commercial insurance but dominates in the property insurance fields. In the United States, mutual companies dominate in the field of life insurance, but this is not the case in Great Britain.

In property insurance, mutuals play a minor role but are a growing factor in the various forms of liability insurance, especially in the United States. The reciprocal or interinsurance exchange appears to be peculiar to the United States. Operations are managed by an attorney in fact through whom members exchange certificates of insurance, each member thus becoming both insured and insurer. Its use is not extensive and is confined to the property insurance field, primarily the automobile lines.

Field organizations are maintained through a variety of channels. The functions include selling, inspection of property, to some extent underwriting (in this sense, acceptance or rejection of applications or conditions of acceptance to be imposed), and investigation and settlement of claims. Home offices of insurers may, of course, maintain direct contact with the public through their own salaried employees. Inspection and claims are frequently handled in this way, but sales only rarely. Branch offices or, particularly in the United States, general agencies usually stand between the insurer and the sales force. The British counterpart of branch offices in the United States is a chain of branches subject to effective head office control. Only in the United States did the insurance agency become a full-time business or profession. Elsewhere direct selling or the use of part-time agents remained the rule. In Great Britain, bankers, merchants and other business or professional men act as agents, and even large owners of property may receive commissions on the insurance sold, in effect, to themselves, a practice frowned upon in the United States.

The tendency toward association is highly developed in the insurance business—partly because of the highly technical character of some phases of the business and the need for exchanging ideas, and partly because of the desire of various groups within the business to establish and maintain standards. A desire to provide protection against damaging legislation played a part in association activities in the United States. In the United States, also, state statutes encouraged property insurers to associate for rate-making purposes.

A number of associations exist in England to watch over the special interests of sections of the business. Their names alone indicate the field of their operations: the Accident Offices association, the Fire Offices committee, the Life Offices association and the Industrial Life Offices association, the Institute of London Underwriters and the Liverpool Underwriters association, the Mutual Insurance Companies association. Perhaps overriding all these is the British Insurance association, comprising insurance companies, tariff and nontariff, mutual and proprietary, transacting all or any class of insurance or reinsurance business. It handles problems of wide and general common interest. Membership is restricted to companies with head offices in the British Commonwealth or Republic of Ireland.

The importance of insurance in modern economies, its technical nature and the difficulty faced by most persons in attempting to appraise contracts and the companies offering them have led to some measure of government regulation in all countries. The extent of the regulation varies from country to country. In the United States it is quite detailed. Until the 1940s, regulation had been regarded as coming within the exclusive province of state and local governments. Then the U.S. supreme court in 1944 (*United States* v. *South-Eastern Underwriters Association et al.*, 322 U.S. 533) ruled that insurance is commerce and, since insurance transactions cross state lines, the business falls within the regulatory powers of congress under the commerce clause of the constitution. Congress then adopted public law 15, giving the states until Jan. 1, 1948 (later extended to June 30, 1948), to revise their regulations to meet certain standards laid down in the act. The system of state regulation as revised apparently proved acceptable to congress.

In contrast to extremely detailed regulation in the U.S., British insurance is subject to only a minimum, pursuant to the Companies act, 1948, and the Assurance Companies act, 1958.

Social Insurance.—The second broad division of the insurance field, social insurance, is of much more recent origin than voluntary or commercial insurance. The shift from an agricultural and handicraft economy to modern industrial society in the western world brought with it a new type of social insecurity for which social insurance was evolved as at least a partial solution. Germany, under Prince Otto von Bismarck, was the first nation to establish a system of social insurance on a national scale. Sickness insurance, compensation for industrial injuries, old-age and invalidity insurance were included in the original program, and survivors' insurance was added later. The schemes initiated in Germany relied upon existing institutions for their administration in so far as possible—funds established by community, industry or occupation in sickness insurance, workmen's compensation by trade associations, and old-age and invalidity insurance by territorial institutes. All funds were mutual, and costs were shared by employer and worker or were borne by the employer alone.

The principle of utilizing existing institutions generally was followed in other countries. Compensation for industrial accidents received world-wide acceptance, but provision for insurance varied widely. Compulsory sickness insurance was adopted in many European countries before World War II. At the same time a shift from noncontributory pensions to compulsory old-age insurance was well under way. Twenty-one countries, 16 of them in Europe and 5 in Latin America, had such plans, and in many cases survivors' insurance and invalidity coverage had been added. Several European countries followed England's lead in adopting unemployment insurance.

Social insurance made its appearance in the United States during the 1930s. Following the adoption of old-age pension plans by a number of the states and an unemployment insurance law by one (Wisconsin), the Social Security act of 1935 provided for federal financial participation in state old-age pensions, aid to dependent children and to the blind, federal old-age and survivors' insurance, and inducement to the states to adopt unemployment insurance plans. After 1935, amendments to the act increased benefits and extended the scope of old-age and survivors' insurance.

See also SOCIAL SECURITY; LIFE INSURANCE; ACTUARY; ANNUITY; FIRE INSURANCE; MARINE INSURANCE; CASUALTY INSURANCE; GROUP INSURANCE; CREDIT INSURANCE; AVIATION INSURANCE; MOTOR VEHICLE INSURANCE; UNEMPLOYMENT INSURANCE; LLOYD'S. The article VETERANS ADMINISTRATION, U.S., includes some discussion of insurance. Some of the institutions that anteceded social insurance are treated in the article POOR LAW.

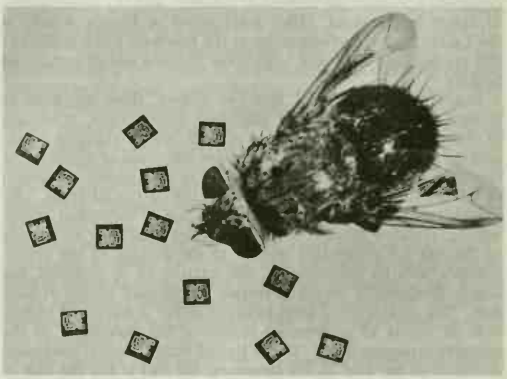
INTEGRATED CIRCUIT. An integrated circuit consists of a number of electronic circuit elements fabricated and inseparably associated on or within a continuous body to perform an electronic function. Before the advent of integrated circuits, electronic circuits were composed of separate devices, each encapsulated in a package of glass, metal, ceramic, or plastic, connected together by soldering or welding (often using printed circuit boards) to perform an electronic function such as amplification or switching. Component devices of a circuit were either active (*i.e.*, exhibiting electrical gain) or passive. Passive devices include the resistor, capacitor, inductor, transformer, diode, and crystal. The first useful active electronic devices were vacuum tubes, later largely supplanted by transistors, which, in the early 1950s, heralded an electronic revolution. Many other active solid state devices followed (*see* TRANSISTOR). But in the early 1960s, a scant ten years after the introduction of the transistor, a second electronic revolution occurred with the impact of integrated circuitry.

An integrated circuit is composed of many unencapsulated devices, active and passive, interconnected in a package to perform an electronic function. A significant feature is that the component devices are often fabricated in or on the same piece of solid material. Sometimes referred to as microcircuits, integrated circuits can be miniaturized to the point where a circuit composed of more than 25 active and passive devices can fit within the letter "O" of this type.

Among the many advantages of integrated circuits, particularly for use in such items as hearing aids, space vehicles, and computers, are their great reductions in size and weight. Also, the uniformity of package shapes facilitates system interconnection and heat dissipation. Although a great many steps enter into the fabrication of an integrated circuit, many circuits can be processed simultaneously so that the cost per circuit may be low. A very important aspect of integrated circuits is improved reliability, a direct consequence of more uniform process technology and simplified interconnections.

The semiconductor parts (generally silicon) of an integrated circuit are fabricated starting with a large crystal about 1 in. in diameter and 12 in. long, which is cut into round wafers about 0.01 in. thick. A typical process for forming a P-N junction diode on a silicon wafer begins with the silicon substrate part of a wafer (N+) containing a high concentration of a donor impurity (phosphorus). A thin layer (about 0.001 in.) of N-type silicon containing fewer donor impurities is grown epitaxially on one side of the wafer by the pyrolytic decomposition at 1,200° C of a gas such as silicon tetrachloride, $SiCl_4$, containing a trace of phosphorus trichloride, PCl_3. The water is then oxidized in steam at 1,000° C, forming a 1-μ-thick layer of silicon dioxide, SiO_2. Next, a layer of photoresist (a photosensitive organic emulsion) about 1μ thick is spread on the surface. A glass photographic plate (mask) with the desired pattern is placed on top of the photoresist layer and illuminated. The photoresist polymerizes in a pattern duplicating that on the photographic plate, and the unpolymerized photoresist is washed away. A hydrogen fluoride (HF) acid solution is then used to etch away the exposed SiO_2, and the resist layer is removed to leave a patterned SiO_2 layer, with holes typically 0.0001 to 0.01 in. wide. The wafer is next placed in a 1,200° C diffusion furnace in an atmosphere containing an acceptor impurity vapour (boron as B_2O_3). This impurity diffuses into the silicon only where the SiO_2 layer is missing and is in turn covered by a SiO_2 layer. Another photoresist sequence (with a different mask) is used to etch contact holes through the SiO_2 layer. A metal film (aluminum) 1μ thick is deposited over the wafer surface by vacuum evaporation or sputtering. Another photoresist sequence is used to pattern the metal film, which extends along the surface to connect to other devices on the wafer.



U.P.I.—COMPIX

MAGNIFIED PHOTOGRAPH SHOWING A COMMON HOUSEFLY, ABOUT ½ IN. LONG, IN COMPARISON WITH TINY INTEGRATED CIRCUITS

The various devices (transistors, resistors, etc.) can be isolated from one another in the silicon by their (lower) P-N junctions or by thin glass layers. Also, thin-film resistors (*i.e.*, nickel-chromium, tantalum, or tin dioxide, about 0.1μ thick) may be deposited on top of the SiO_2 layer. By successively depositing patterned metal, dielectric, and metal layers on the SiO_2, thin-film capacitors are formed on top of the SiO_2 layer.

The finished wafer, composed of about 60 to 100 circuits, is separated into individual circuit chips by scribing the surface between patterns with a sharp, hard point and breaking (much the same as a diamond is cleaved). A chip is soldered down to a package, and fine wires (0.001 in. in diameter) are connected between the integrated circuit and the package terminal leads. The package is capped by welding, soldering, glassing, or plastic molding. Sometimes more than one silicon chip is used to make the circuit, and miniature passive components may be included in the package.

In contrast with a semiconductor integrated circuit, a thin-film integrated circuit utilizes a glass or ceramic substrate. Thin-film components are deposited on the substrate and patterned, and other miniature components are attached.

INTEGRATION AND MEASURE, in mathematics, represent ideas which have developed from the need of primitive people to express the amount, degree and intensity of objects and events in the physical environment. As mathematical thinking developed beyond concrete description, the notions of integration and measure became increasingly abstract. An attempt will be made here to trace this metamorphosis, assuming an understanding of such topics as discussed under ANALYSIS; ANALYSIS, ABSTRACT; ANALYSIS, COMPLEX; CALCULUS, DIFFERENTIAL AND INTEGRAL.

The abstract concepts of measure and of integration are best understood in the light of the historical evolution and growth of the problem of measure. This problem always has been present in everyday life as well as in organized acquisition of knowledge; *i.e.*, in science. It pertains to "measures" of such properties as the length of a curve (rectification), area of a surface (quadrature), volume of a solid (cubature), mass or weight or electric charge of a body, probability of a random event, and so on. Yet the abstract concept of measure, of which the preceding "measures" are but particular concrete cases, has been isolated only in the 20th century. The corresponding evolution may be loosely divided into several periods, each characterized by its attitude toward the problem of measure.

The Empirical Period.—The purely empirical period began with prehistory and lasted until the 6th century B.C. The most advanced organized knowledge of this period was Babylonian and Egyptian, providing precise and correct rules for finding areas and volumes of such geometric figures as the triangle, trapezoid and circle. For the Babylonians π equalled 3 (this value of π is also found in the Old Testament) and for the Egyptians π equalled $256/81$ ($= 3.160\ldots$). They also had correct rules for the parallelepiped, prism, pyramid and circular cylinder, thought of in concrete terms—mainly as grain storage containers. The ancient Egyptians even had a correct rule for measuring the frustum of a square pyramid.

Apparently these rules were discovered empirically. To become "proven" mathematical propositions, deduced from a set of definitions and postulates, they had to await the "Greek miracle": the emergence of organized abstract thinking in Greece which includes the earliest known treatment of mathematics as a deductive discipline. Available information prompts some historians to attribute the birth of abstract mathematics to Thales (6th century B.C.), one of the Seven Wise Men of ancient Greece.

The Greek Period.—This period began with Thales and lasted until about 200 B.C. By the 5th century B.C. problems of quadrature and cubature were so popular that Aristophanes in his satirical comedy *The Birds* alludes to the quadrature of circles, while the problem of duplication of cubes is attributed to the Delphic oracle. The first abstract proofs of rules for finding some areas and volumes are said to have been developed by Eudoxus of Cnidus (*c.* 400–*c.* 347 B.C.). His method of approximation was developed and exploited by Archimedes (*c.* 287–212 B.C.), called the greatest mathematician of antiquity. This method, called the method of exhaustion in the 17th century A.D., was at the root of all further developments of the mathematical problem of measure. The method culminated in the 19th-century isolation of the concept of Riemann integration, defined by means of approximating Riemann sums (which in all justice could be called Eudoxus or Archimedes sums or, as shall be seen later, Cauchy sums).

In modern terms, the method of exhaustion applied to surfaces, for example, may be stated as follows: Let S be a surface of unknown area s. Denote by S' a surface of known area s' contained in S and denote S'' a surface of known area s'' containing S; thus $s' < s < s''$. The approximating surfaces S' and S'' are polygons or sums of slices, mainly trapezoidal or rectangular, selected by Eudoxus and by Archimedes according to the particular figure S. In fact, sums of rectangular slices (whose area is particularly simple to compute) were to become predominant from the 16th century A.D. on. To complete the proof Archimedes used the following proposition: If a known area a is such that for every positive ϵ there exist surfaces S' and S'' with $s' < a < s''$ and $s'' - s' \leq \epsilon$, then $s = a$. Archimedes did not isolate this proposition, and proved it in concrete geometric terms for every particular figure he considered by a double *reductio ad absurdum* (double, because negative numbers were not available to him): If $s < a$, take $\epsilon < a - s$ and if $s > a$ take $\epsilon < s - a$; in either case a contradiction is reached, so that $s = a$. The method is not complete, for it does not say how to find the value a. In fact, Archimedes filled the gap, but the letter to Eratosthenes which told about what is sometimes called the Archimedes method remained unknown until 1906. In the letter Archimedes gave his heuristic approach: A surface is thought of as a sum of lines to each of which is applied the lever principle.

The idea of sum of lines was rediscovered in Italy in the 16th century. Hindu-Arabic numerals were adopted. Algebra was stimulated, letters began to stand for quantities, and symbols were introduced to denote operations. Inexorably, through the indivisibles period to the emergence of calculus, these representations led to a new attitude, an analytic one in lieu of the geometric attitude of the Greeks.

The Indivisibles Period.—This period extended from 1615 to about 1670, heavily influenced by Archimedes whose works became available in 1544 in Greek and in Latin. The concept of integration gradually emerged, but neither in Archimedean nor in modern dress—especially in England; there, integration became for a time not a primary operation but the inverse of the operation of differentiation.

After S. Stevin and other followers of Archimedes came the pioneering work of J. Kepler, *Stereometria doliorum vinorum* (1615; "Solid Geometry of Wine Barrels"). From then on and until the 19th century, Archimedean rigour was abandoned in favour of an intuitive "infinitesimal" reasoning. For Kepler the circle consisted of an "infinity" of infinitesimal triangles with common vertex at the centre; the sphere consisted of an "infinity" of pyramids, and so on. But he obtained over 80 new results for areas and volumes. The language of infinitesimals or method of indivisibles was then codified by B. Cavalieri in his *Geometria indivisibilium continuorum nova quadam ratione promota* (1635). For the first time in the history of the problem of measure, instead of measures of specific geometric figures, general principles for quadratures and cubatures were announced. While not proved rigorously, the principles were at least "justified" in the language of infinitesimals.

The Cavalieri principle, say for quadratures, may be stated as follows: If the ratio of lengths of sections of two surfaces generated by a straight line which moves parallel to a fixed direction is a constant then the ratio of their areas is this constant. The justification of this principle in the language of infinitesimals can be described in modern terms as follows: Associate to every real-valued nonnegative function f defined on a set A of reals its ordinate set in the (x,y)-plane; that is, the set of all points (x,y) such that x belongs to A and y varies from 0 to $f(x)$. When A is the segment $[0,a]$, then the ordinate set of f is the surface in the x,y plane whose boundaries are the vertical lines $x = 0$ and $x = a$, the horizontal line $y = 0$, and the graph of the function f. For two such functions f and g on $[0,a]$ with co-ordinate sets $S(f)$ and $S(g)$ of areas $s(f)$ and $s(g)$, the ratio of the sums of equidistant ordinates $\sum_{k=0}^{n-1} f(ka/n)$ and $\sum_{k=0}^{n-1} g(ka/n)$ can be made as close as desired to the ratio $s(f)/s(g)$ of the areas, provided n is sufficiently large. (The question of existence of these areas was not raised until the middle of the 19th century.) Therefore, letting n approach infinity, the unknown ratio is the "limit" of the ratio of the sums of ordinates. However, the concept of limit was not isolated at that time and Cavalieri actually took n to be directly equal to infinity. Thus appears the *summa omnium linae* (sum of all lines). However, some mathematicians of this period such as B. Pascal and G. P. Roberval spoke of "rectangles with infinitely small bases" instead of lines.

During the indivisibles period the method of indivisibles yielded a very large number of special integrals as quadratures, cubatures and centres of gravity. Most were formulated geometrically. But already more abstract algebraic formulations were apparent: P. Fermat and Cavalieri integrated x^n for rational

$n \neq -1$; Gregoire de Saint Vincent integrated it for $n = -1$ in a geometric form at once recognized as the logarithmic function; and Pascal integrated $\cos x$. Fermat, Pascal and J. Gregory geometrically manipulated changes of variables and integrations by parts. In fact, geometric methods, formulations and results were gradually made analytic. Pascal first discussed the types of sums he would need and then only computed them in the concrete geometric case under consideration. J. Wallis in *Arithmetica infinitorum* (1655), which has to be translated as "infinitesimal" algebra, started straight from algebraic grounds, introducing infinite series and infinite products, and N. Mercator discovered (1668) the series expansion of $\log (1 + x)$.

The impetus and the tools for abstraction were provided by the growth of algebra, the birth of analytic geometry with R. Descartes' *Geometrie* (1637), Fermat's *Isagoge* (written before 1637) and the birth and growth of kinematics. Consideration of time as a concept in kinematics and the notion of abscissa in analytic geometry led to a gradual emergence of the idea of independent variable. Velocities and slopes of tangents led to the concept of differentiation. Performance of rectifications, such as that of parabolic arcs, forged a first link between differentiation and integration, because rectification of curves $y = f(x)$ was reduced to the quadrature of $\sqrt{1 + [f'(x)]^2}$, where $f'(x)$ is the derivative of $f(x)$. In fact, integration lost its predominant role in favour of differentiation. The basic link was provided by the recognition that differentiation and integration are inverse operations, to be found in I. Barrow's *Lectiones geometricae* (1670). While a crowning of the indivisibles period, Barrow's work also represented the dying spirit of the period. He began with kinematical considerations which seemed to lead at once to the basic link. Yet, the relation between differentiation and integration was given much later in two widely spaced propositions, and in geometric terms; the derivative in terms of slopes of tangents and the integral in terms of areas.

The Calculus Period.—This period extended from about 1670 to the beginning of the 19th century, beginning with the creation of the calculus by G. W. Leibniz and I. Newton. Newton, influenced by his teacher Barrow and his preoccupation with dynamics, used a universal independent variable conceived primarily as time; thus, he had no concept of functions of several variables, hence no partial derivatives. The primary concept was that of fluxion (derivative) and arose from kinematical considerations. The concept of integral was not isolated and no symbol for integration was introduced. His first basic problem was to find fluxions. Integration was treated in a geometric form as a search for fluents (antiderivatives, primitives, indefinite integrals), functions whose fluxions are given.

Newton depended mainly on the fact that the derivative of a variable area $F(x)$ under a curve is the ordinate $f(x)$ of this curve. Moreover, for Newton integration was only a particular case of his second basic problem: Given an equality relation containing fluxions, find the relation for fluents (solve ordinary differential equations). He solved them formally by means of series.

Leibniz, influenced by Pascal, conceived the derivative as the slope of a tangent, and the integral as *summa omnium linae*. The main purpose of all his activity is to devise a universal language, that is, a general formalism for the acquisition and organization of knowledge. He largely succeeded in the creation of such a formalism for the calculus. In fact, the present formalism is still essentially and properly his, including the integral symbol (a stylized form of the letter S standing for *summa omnium*). His are the terms constant, variable, parameter and (with the help of Johann Bernoulli) the terms function and integral.

An unpleasant fact is that in the third quarter of the 20th century, freshman college calculus was still being taught largely in the spirit of 1700 with a thin modern varnish, ignoring the 250 years of evolution of mathematical thought which followed.

The heroic years of the calculus at the end of the 17th century saw the constant flow of new results from Leibniz and his school: Jakob Bernoulli, Johann Bernoulli, G. F. A. de l'Hospital. During the 18th century, C. Maclaurin pursued and developed Newton's ideas and attempted to clarify them in his *Treatise of Fluxions* (1742), while L. Euler pursued further the ideas of Leibniz and his school in his *Introductio in analysin infinitorum* (1748) and attempted to found the calculus upon an obscure passage to the limit starting with the calculus of differences.

Mathematicians of the 18th century devoted little effort to the shaky foundations of the calculus, apparently happy with the powerful tools at their disposal, the fecundity of the methods, the beauty and consistency of the results. Discussions about the metaphysics of calculus were left to philosophers and theologians, among whom figured prominently Bishop George Berkeley. Then, the whole subject of metaphysics of calculus vanished into thin air with J. d'Alembert's two articles on "Limite" and "Différentielle" in *Encyclopédie* (1751–65). At last was isolated the concept of limit, which runs as an almost invisible thread in the fabric of infinitesimals as woven since Stevin and others at the turn of the 17th century, and the concept of differentiation was finally defined rigorously in terms of limits. Yet, after d'Alembert, J. Lagrange still tried to define integration in terms of Newton's conception of a function as a power series.

The Analysis Period.—A new period opened with A. L. Cauchy's *Calcul infinitésimal* (1823), at the basis of which was the concept of limit. Differentiation was defined by a passage to the limit. At last, the integral was defined directly and in purely analytic terms by returning to the very essence of the method of exhaustion as follows: Let $f(x)$ be a bounded function defined for $a \leq x \leq b$. Divide the interval $[a,b]$ into n subintervals by means of points $a = x_0 < x_1 < \ldots < x_n = b$. Form the Eudoxus-Archimedes-Cauchy sums (called nowadays Riemann sums) $\sum_{k=0}^{n-1} f(t_k)(x_{k+1} - x_k)$ with $x_k \leq t_k \leq x_{k+1}$. The limit of these sums as the largest length of the subintervals converges to zero is, by definition, the integral $\int_a^b f(t)dt$ of the function f on $[a,b]$, provided this limit exists and is independent of the choice of the t_k.

A new way of thinking was born; existence of integrals as well as that of derivatives was no longer a question of faith but a problem to be studied. Cauchy gave an incomplete proof of existence of integrals of continuous functions, and his proof was completed only in 1875 by J. G. Darboux. Meanwhile, G. F. B. Riemann in 1854 (published in 1867) gave necessary and sufficient conditions for the existence of the integral called Riemann integral, and showed that continuous and piecewise monotone functions satisfy these conditions. Instead of Riemann sums, Darboux introduced the upper and lower Darboux sums $\sum_{k=0}^{n-1} M_k(x_{k+1} - x_k)$ and $\sum_{k=0}^{n-1} m_k(x_{k+1} - x_k)$ where M_k and m_k are, respectively, the least upper and the greatest lower bounds of $f(x)$ as x varies between x_k and x_{k+1}. The passage to the limit yields the upper and lower Darboux integrals. These two integrals coincide if and only if the bounded function f is Riemann-integrable on $[a,b]$.

Meanwhile, the general concept of a real-valued function of a real variable which appeared in a more or less vague or restrictive form throughout the calculus period was finally isolated by P. G. L. Dirichlet (1829). Dirichlet examined the problem of convergence of Fourier series. Since the coefficients of these series are given by integrals of the form $\int_a^b f(x) \cos nx dx$ and $\int_a^b f(x) \sin nx dx$, knowledge about Fourier series expanded with the evolution of the concepts of integration and of function. From Dirichlet and Riemann on, the knowledge of trigonometric series and, more generally, of harmonic analysis gained in depth and in extension as understanding of integration and the functions increased.

In fact, modern set theory, which changed the whole outlook on measure and integration, began in 1872 with G. Cantor's investigation of the structure of some exceptional sets of trigonometric series: sets S such that if a trigonometric series

$\sum_{n=-\infty}^{+\infty} c_n e^{inx}$ converges to zero except at the points of S, then all $c_n = 0$. The evolution of set theory between 1872 and 1890, due primarily to Cantor's genius, together with the parallel investigation of the system of reals and of functions of reals by such mathematicians as J. Dedekind, K. Weierstrass, P. du Bois-Reymond and V. Dini, brought on the "Great Mathematical revolution."

The revolution occurred at the turn of the 20th century and can be compared only to the birth of mathematics as a deductive discipline some 25 centuries ago. The problem of foundations was revived but applied to the tremendous wealth of accumulated knowledge at a level of abstraction far beyond that known to the ancient Greeks. In particular, the problem of measure was no longer confined to a few special sets—the geometric figures available to Eudoxus or Pascal. Moreover, the very nature of the problem was different.

Eudoxus' or Pascal's problem was to find the measure (area, volume) of some specific geometric figure. The existence of this measure was a question of faith and it was approximated by sums of measures of simple figures. The new problem was to define a measure for as large a class of sets as possible by means of such approximations. The first attempts were made in 1884–85 by A. Harnack, O. Stolz and Cantor. They did not succeed because they used only approximations from above; they assigned to any set S the greatest lower bound of sums of ordinary measures of simple sets—intervals, rectangles, parallelepipeds, whose finite unions cover S.

The outer content so defined does not correspond to the intuitive idea of measure, for it is not additive: in everyday experience as well as in experimental science, the "measure" of a union of two disjoint sets is the sum of their "measures." For example, the volume (or mass) of two disjoint bodies is understood as the sum of their volumes (or masses). This requirement was recognized by G. Peano and C. Jordan who introduced approximations both from above and from below. To a set S contained in a bounded interval I they assigned also its inner content (the difference between the ordinary measure of I and the outer content of S). If the inner and outer contents of S are the same, then their common value defines the content of S. This content measure is additive. However, the most important types of sets encountered in analysis, such as the set of all rationals or general open sets, have no content. Thus the content measure is of limited use.

The Extension Period.—The extension (or theory of measure) period opened in 1898 with E. Borel, the modern Eudoxus. It has been characterized by the extension of the idea of measure to wider and to more abstract classes of sets and the parallel extension of the idea of integration to wider and to more abstract families of functions until both ideas coalesce. It was stimulated by and intricately interwoven with the explosive growth of general topology following M. Fréchet's thesis in 1902.

At the root of the theory of measure lie a few crucial remarks by Borel in his *Leçons sur la théorie des fonctions* (1898). While studying series of functions Borel found the need for a measure such that sets whose measure is not zero are not countable. Thus, he introduced the Borel measure on the Borel field, prototypes of all measures and all σ-fields to follow.

From now on, it will be convenient to use the following terminology: Unions of disjoint sets will be called sums and then the symbol $\cup$ for union will be replaced by Σ. Countable will mean finite or denumerable. Countable (or finite) set operations are complementations and taking countable (or finite) unions and intersections. A σ-field (or field) of sets is a class of sets closed under countable (or finite) set operations.

Borel began by extending the ordinary measure on intervals to a measure on open sets, as follows: Cantor had shown that every open set G of reals is a countable sum of open intervals I_j and Borel realized that the "natural" extension consists in assigning to G the sum of ordinary measures of its constituent intervals I_j. Note that if G is not bounded this sum may be infinite; but it always exists. By indefinite iteration of countable set operations and the same extension procedure, he then extended the class of open sets and their measure to the class of Borel sets and their Borel measure. This class is a σ-field (the smallest σ-field containing the class of open sets), and this measure is σ-additive; the measure of a countable sum of sets is the sum of their measures. From then on, the Borel field of Borel sets in any topological space will be the smallest σ-field containing the topology, that is, the class of open sets in the space. (In fact, some authors use the term Borel field as a synonym for σ-field.)

The Archimedes of the extension period was H. L. Lebesgue. He took the decisive step in his thesis *Intégrale, aire, volume* (1902), which he immediately applied to trigonometric series (1903), and pursued further in *Sur l'intégration des fonctions discontinues* (1910). Lebesgue combined the ideas of his immediate predecessors, Jordan and Borel, and created and exploited powerful tools of modern measure and integration. In fact, contemporary theory of measure still dances to Lebesgue's tunes. The evolution of his ideas, methods and results consisted primarily in the gradual shedding of their extraneous coverings.

The Lebesgue measure is defined by extending the ordinary measure on intervals by means of outer and inner Lebesgue measures, exactly as the Jordan content was defined, except that coverings by countable unions of intervals replace coverings by finite unions. The intervals are one-dimensional or N-dimensional, and the same method applies. Then the Lebesgue integral of a function $f \geq 0$ defined on a set becomes simply the Lebesgue measure of the ordinate set of the function, provided this set is Lebesgue-measurable. As may be expected, every Riemann-integrable function is Lebesgue-integrable, but the converse is not true. Riemann's integrability condition for bounded functions f becomes: the discontinuity set of f is of Lebesgue measure 0. Thus, the famous Dirichlet function $f(x) = 0$ or 1 (according as x is irrational or not) which is Lebesgue-integrable on every bounded interval is not Riemann-integrable.

The main contribution of Lebesgue does not reside in the above concepts. For example, the Lebesgue measure is simply the completed Borel measure; that is, a Lebesgue-measurable set is a Borel-measurable set up to a subset of a set of Borel measure 0. What really counts is the discovery and use by Lebesgue of the properties of his concepts of measure and of integration.

Let us mention that, using the Lebesgue approach, the problem of finding a process of integration which includes both that of Leibniz (*summa omnium*) and that of Newton (primitive) was solved by A. Denjoy (1912) and also by O. Perron (1914).

The cleaning up of Lebesgue's ideas was essentially achieved in the 15 years or so which followed his thesis. It yielded a general answer to the problem of measure for areas, masses, probabilities, . . . and finally isolated its conceptual substance. However, the answer and the substance were to be formulated in terms very far removed from the everyday experience. The steps in the cleaning-up process included the generalization which stemmed from T. J. Stieltjes and was due to J. Radon, and the abstraction which began with Fréchet (1915) and with C. Carathéodory (1918).

Stieltjes, in *Recherches sur les fractions continues* (1894), in order to express the limit of a particular sequence of analytic functions, replaced (in the approximating sums for Riemann integration) lengths of intervals by masses spread on them. He introduced a distribution of masses by means of a nondecreasing function g. It assigns to every interval $[a,b]$ the increment $g(b) - g(a)$ of the function g; if $g(x) = x$ then the increment reduces to the length $b - a$ of the interval. Thus, in Riemann or in Darboux sums the increments $x_{k+1} - x_k$ are replaced by the general increments $g(x_{k+1}) - g(x_k)$, and the usual passage to the limit of the so-formed Riemann-Stieltjes or Darboux-Stieltjes sums yields Stieltjes integrals. Then, in 1909, F. Riesz, solving a problem set by J. Hadamard, discovered that these Stieltjes integrals $\int_a^b f\,dg$ are the most general nonnegative continuous linear functionals on the space of all continuous functions f defined on the bounded interval $[a,b]$.

In 1913 Radon, working in N-dimensional euclidean spaces, combined Lebesgue's ideas with the Stieltjes generalization of

ordinary measure and integration, and with Riesz's discovery. Thus appeared Lebesgue-Stieltjes measures and integration. Lebesgue-Stieltjes measures are defined like the Lebesgue measure, except that the ordinary measure on intervals is replaced by the mass spread on them given by the increments of nondecreasing functions. Lebesgue-Stieltjes integrals of nonnegative functions are then the masses spread on the co-ordinate sets.

In 1915 Fréchet eliminated the topology for the measurable sets and the integrands, while Carathéodory (1914, 1918) got rid of topology for the extension of measures. At last, the concepts of measure and of measurability were isolated. The following points summarize the basic concepts of the theory of measure:

1. A set Ω with a σ-field $\mathcal{A}$ of its subsets (to be called measurable sets) is a measurable space $(\Omega, \mathcal{A})$. A function f on Ω, say, to the real line R is said to be measurable if the inverse images by f of Borel sets in R are measurable. (The inverse image by f of a set A is the set of all points ω belonging to Ω such that the values $f(\omega)$ of f at these points belong to A.) The tremendous advantage of a family F of all measurable functions on a measurable space, as compared, say, to the family of all continuous functions on a topological space, is that not only is F closed under arithmetic operations but it is also closed under sequential limits. In particular, if there is a topology on Ω, and $\mathcal{A}$ is the σ-field of Borel sets in this topological space, then F contains the family of continuous functions on it. This is the abstraction of Borel's set-up.

Denote measurable sets by A (with or without subscripts) and to every such A assign its indicator $I_A = 1$ on A and 0 elsewhere. A measurable function with a finite number of distinct values $x_1, \ldots, x_n$ is called a simple function and is denoted by $\sum_{k=1}^{n} x_k I_{A_k}$.

2. A measure μ on a class $\mathcal{E}$ of sets in a space Ω is a nonnegative countably additive function of sets (not necessarily finite). If, to simplify the statements, Ω is one of the sets of the class, then this measure can be extended to an outer measure μ^0 on all sets A in Ω by assigning to every A the greatest lower bound of sums of measures of sets of $\mathcal{E}$ whose countable union covers A. This is the abstraction of the Lebesgue outer measure. The restriction of the outer measure μ^0 to μ^0-measurable sets yields then the extension of μ on $\mathcal{E}$ to a measure on the σ-field (containing $\mathcal{E}$) of μ^0-measurable sets; a μ^0-measurable set B is such that $\mu^0 C = \mu^0(B \cap C) + \mu^0(B^c \cap C)$ for all sets C in Ω (the symbol $\cap$ means intersection and the superscript c means complement of). The μ^0-measurable sets are the abstraction of Lebesgue-measurable sets. The extension is unique provided the initial measure given on a field $\mathcal{E}$ is σ-finite; that is, Ω is a countable union of sets of $\mathcal{E}$ with finite measure.

3. The triplet $(\Omega, \mathcal{A}, \mu)$ where μ is a measure on the σ-field a is a measure space. The integral $\int f d\mu$ of a finite simple function $f = \sum_{k=1}^{n} x_k I_{A_k}$ is defined as the (Eudoxos-Cauchy-Riemann-Stieltjes-Lebesgue-Radon) sum $\sum_{k=1}^{n} x_k \mu A_k$. Every nonnegative measurable function f is the limit of a nondecreasing sequence of nonnegative simple functions f_n. Set $\int f d\mu = \lim_n \int f_n d\mu$. This limit always exists but may be infinite. It is independent of the choice of sequences $f_n \uparrow f$. Every measurable function f can be written as a difference of two nonnegative measurable functions: $f = f^+ - f^-$ with $f^+(x) = f(x)$ or 0, and $f^-(x) = 0$ or $-f(x)$, according as $f(x) \geq 0$ or $f(x) < 0$. The integral $\int f du$ is the difference of the integrals of f^+ and of f^-, provided it exists, that is, is not of the form $+\infty - \infty$. The function f is μ-integrable if its integral exists and is finite. Since the absolute value $|f| = f^+ + f^-$, it follows that f is integrable if and only if $|f|$ is integrable. This is the abstraction of the constructive definition of the Lebesgue integral.

The importance and usefulness of this integration is due to its monotone convergence property, which means that for nondecreasing sequences of nonnegative measurable functions f_n, passage to the limit and integration commute; in symbols, if $0 \leq f_n \uparrow$ as $n \to \infty$, then $\lim_n \int f_n = \int \lim_n f_n$. All other convergence properties of this integration, in constant use in analysis, follow from it.

4. The indefinite integral ϕ on measurable sets A of a function f whose integral exists is defined by $\phi(A) = \int_A f d\mu = \int f I_A d\mu$. This is the abstraction of the Lebesgue indefinite integral. Its fundamental property which may serve as a descriptive definition of integration, first obtained by Lebesgue then generalized by Radon and finally abstracted by O. Nikodym, is as follows: On a σ-finite measure space, a set function ϕ is indefinite integral of one and only one function f but defined only up to values on a μ-null set if, and only if, ϕ is a difference of two measures, and is σ-additive and μ-continuous, that is, $\phi(A) = 0$ whenever $\mu(A) = 0$. This property plays a basic role in the theory of measure and, especially, in the theory of probability.

The foregoing (1–4) represent the basic set-up of the theory of measure and also yield the foundations of probability theory. Also deserving mention is the concept of stochastic independence, which was, and to a great extent still is, essential to the evolution of probability theory since its inception in 1654 by Pascal and Fermat. It too became measure–theoretic with the creation and abstraction of finite and infinite product measures by Lebesgue and by P. J. Daniell.

Throughout the evolution of the problem of measure, integration appears as means for finding measures of sets or assigning measures to sets. Thus, seen in the historical light, measure, integration and the related concepts of measurable sets and measurable functions ought to have coalesced in one primary concept from which they would be derived. This was done by Carathéodory and Daniell by cleaning up the extension procedure.

Carathéodory (1918) emphasized the measure as the primary concept. Given a σ-finite measure μ on, for example, a field of sets A, it is extended uniquely to a measure on a σ-field as in 2 above. It is also used to define a product measure of μ with the ordinary measure on intervals (the product measure of a rectangle, with sides A in Ω and interval I in R, is the product of the measures of its sides) and then similarly extended on the corresponding σ-field in the product space $\Omega \times R$. Thus are formed measurable sets in Ω with the extended measure on them and measurable sets in $\Omega \times R$ with the corresponding product measure on these sets. The ordinate set of a function $f \geq 0$ is a set in $\Omega \times R$. The function is measurable when the ordinate set is measurable and the integral of f is the measure of its ordinate set. If f is not of constant sign, write $f = f^+ - f^-$ and proceed as in 2 above.

Daniell (1918) abstracted W. H. Young's approach (1911) emphasizing the integral as the primary concept and was followed by S. Banach (1937), M. H. Stone (1948) and the immortal N. Bourbaki. Integration assigns numbers $\int f d\mu$ to functions f; that is, the integral is a functional. The main properties of this functional are that it is linear $(\int (af + bg) = a \int f + b \int g)$, nonnegative (if $f \geq 0$ then $\int f \geq 0$) and, above all, it has the monotone convergence property (if $0 \leq f_n \uparrow f$ then $\int f_n \to \int f$). These three properties suffice: Given a functional $\int$ with these properties on a space F of bounded functions which is a vector lattice (closed under linear combinations and undertaking *suprema* and *infima* two by two), call it an integral on F. The extension problem is to extend this integral on F to as large a family of functions as possible on which the integral still has the same properties. For example, the Cauchy-Riemann integral on the space F of all continuous functions on a bounded interval has the required properties and the extension will yield the Lebesgue integral on the Lebesgue-integrable functions.

The extension procedure is as follows: First extend F to the space U of limits f of nondecreasing sequences of functions f_n in F and then extend the integral by imposing the monotone convergence property so that, by definition, $\int f = \lim_n \int f_n$. This extension is unique. Then extend the integral to the space $-U$ of negatives $-f$ of functions f belonging to U by imposing the linearity property so that, by definition, $\int (-f) = -\int f$. Finally,

approximate an arbitrary function f by functions g in $-U$ and h in U: $g \leq f \leq h$. Define the lower integral of f as the least upper bound of integrals of functions g and the upper integral of f as the greatest lower bound of integrals of functions h. When the lower and upper integrals of f coincide and are finite then take their common value to be the integral of f, to be called integrable function. This is primarily the abstraction of the Darboux approach in Lebesgue's context. The space of integrable functions and the integral on it have the desired properties. In particular, the integrals of integrable indicator functions of sets (equal 1 on the set and 0 elsewhere) define a measure on these sets with the usual properties.

Since about 1930, when integrals of functions with values in a Banach space were introduced by S. Bochner, a further abstraction began and grows. Measures and functions (hence, integrals) take values in more and more abstract spaces instead of taking numerical values as above and various types of convergence are used. Of particular importance are the various stochastic integrals (*see* PROBABILITY AND STATISTICAL THEORY). In fact, the foregoing indications on the set-up of the theory of measure and integration have many variants even in the numerical case. In final analysis, their conceptual substance is the same, but seen from different points of view in various settings, from Eudoxus and Archimedes, through Leibniz and Riemann, to Lebesgue and the present day variations on the same theme. The most important fact is the ever spreading use of the powerful tools these concepts provide for such areas as differentiation theory, boundary problems, ergodic theory, probability theory, group theory, potential theory and harmonic analysis. (ML. LE.)

INTELLIGENCE. The word intelligence (*inter-legentia*) was introduced by Cicero as an almost literal translation of Aristotle's term *dia-noesis*. In the scholastic psychology derived from Aristotle, its use implied a preference for the twofold classification of mental characteristics into intellectual or cognitive (*i.e.*, discriminative and directive) characteristics, as contrasted with dynamic or orectic (*i.e.*, affective and conative), which Aristotle proposed in place of the threefold scheme favoured by Plato. "Intelligence" was thus the abstract quality common to, and peculiar to, all "intellectual" processes; *i.e.*, sensation, perception, memory, imagination, reasoning and the like (*see* PSYCHOLOGY).

In the writings of Herbert Spencer and his successors—Sir Francis Galton, Alfred Binet, Cyril Burt and C. E. Spearman—the word intelligence acquired a standard meaning as a technical term, and has usually been held to imply three basic distinctions: (1) it connotes a cognitive or intellectual capacity, as distinct from other characteristics of the total personality; (2) it implies a general quality (*i.e.*, it enters into all types of intellectual processes and is not specific to any one type of ability); (3) it is an inborn or innate quality, as distinct from abilities acquired through individual experience at home, at school or elsewhere.

In the first instance this concept of an inborn, all-round, general ability was derived mainly from introspection, general observation and philosophical speculation or reason. The conclusions so reached therefore required to be more closely checked and verified by experiment and statistical analysis. The leaders in this scientific approach were Galton (*Human Faculty*, 1883, and later writings), Binet (1890–1911) and students of animal psychology such as C. Lloyd Morgan (1890), E. L. Thorndike (1910) and Wolfgang Köhler (1915). The first effective tests of intelligence (partly suggested by those of Galton) were developed by Binet and his collaborators in France, revised for other countries by Burt (Britain), W. Stern (Germany) and Lewis Terman (U.S.); and the earliest systematic studies (based on the statistical methods introduced by Galton) were those of Karl Pearson, Spearman, Burt, Thorndike and William Brown.

The method adopted by the leaders in their numerous inquiries involved a combination of experimental testing and statistical analysis. It consisted essentially in observing what mental capacities tend to go together, and it led to the theory that there does exist in human beings a single broad mental power (additional to various special abilities) which may be called general intelligence. On comparing the efficiency of various types of test, it appears that intelligence is revealed particularly in good use of verbal symbols, ability to perceive analogies, capacity to abstract and classify, mathematical ability, problem solving and those capacities for understanding relations and causal connections which have been increasingly invoked in experiments on intelligence.

Some educators believe erroneously that intelligence is defined by a mere average score on whatever combination of such subtests a psychologist happens to use. But the exact weights to be given are actually fixed through intelligence's being uniquely and objectively defined by the simple structure criterion in factor analysis. The typical processes in such "highly *g*-saturated" performances can be seen in such modern tests as the Stanford-Binet, the Moray House tests and Raven matrices in Britain, the American Bellevue-Wechsler and A.C.E., the Cattell Culture-Fair scales and the Thurstone Primary Mental Abilities battery.

Biological Conditions.—The effects of age and of inheritance as indicated by results obtained with tests of intelligence (as above defined) have become well understood through the work of such researchers as Terman, Burt and Jean Piaget. There is a rapid augmentation of reasoning and perceptual ability between 3 and 6 years of age, followed by a flattening of the development curve around 14 years of age. Indeed, after 14 there is negligible increase in the basic ability to understand the most general relations. Nevertheless, the individual increases his actual problem-solving capacity by increased knowledge and can better perceive relations in special fields when given close acquaintance with the particular problems of those fields. After the age of about 23 there is actually a slight decline in score on speeded intelligence tests (*i.e.*, as they are usually given), but, if reasoning capacity without speed is tested, no such decline occurs until senility.

No significant differences in intelligence have been found between men and women, and it is not even certain that qualitative differences, as shown by the somewhat higher scores of men in mechanical reasoning and of women in verbal ability, may not be considered as temporary cultural effects. On the other hand, there is ample evidence from comparing the intelligence of identical twins reared in different homes with that of, for example, unrelated children reared together that intelligence is largely inherited. Burt among others presented evidence for the inheritance of differences in intelligence, the correlations and other constants agreeing closely with what would be expected if intelligence (like stature and other graded characters) were transmitted in accordance with the Mendelian laws for multifactor inheritance.

The usually accepted figures, based on the soundest and most extensive studies (*e.g.*, of Barbara Burks in the U.S. and Burt in Britain) employing verbal intelligence tests, assign 75% to 80% of the observed test variation in the general population to genetic factors and the rest to environmental physical and mental conditions and opportunities in home and society. Later work by Cattell, G. F. Stice and N. F. Kristy, using the Culture-Fair tests and improved statistical designs, gives a value of 78:22 to the heredity: environment variance ratio in the general population, but shows that this arises from a 70:30 ratio for intelligence variation *within* families and a 93:7 ratio for variation *among* families. In all these researches, whatever unreliability exists in test administration and scoring tends to inflate the percentage assigned to environment. By contrast, no experimental design has been found for reliably assigning to heredity and environment the true fractions of the appreciable differences of average intelligence test score found among widely different races.

Social and Educational Associations and Uses of Intelligence Measures.—Tests of intelligence are validated in a pragmatic sense by the widespread finding that what is called intelligence in social and educational evaluation turns out to be closely identified with what is measured. Thus children drafted to schools for mental defectives score very low, selective schools average above other schools, and universities above high schools. Test scores are predictive of educational success and of occupational success in most (especially complex) occupations.

Socially there is a slight tendency for higher social class (or complexity of occupation) to be associated with higher intelligence score, even on culture-free intelligence tests, and this fits the school

observation that some trend exists for better mental capacity to segregate to better social status levels. Nevertheless, the greatest absolute storehouse of high mental capacity is the lower middle class—skilled and semiskilled workers—because it is the largest class in sheer numbers.

Since it has been shown that, even in the same social class, less intelligent parents tended, in the first half of the 20th century, to produce a larger fraction of the following generation, it is probable that, apart from dominant genes and a survival rate favouring the intelligent, a decline occurred in average intelligence in industrial countries in the first part of the century. However, a survey around 1950 showed that the negative correlation of intelligence with family size had been much reduced in Britain and had practically vanished in Sweden.

Surveys in the U.S. suggested that the national resources of intelligence, for supplying persons fitted for training as higher scientific, administrative and professional workers, are not so great as once had been thought. Of persons with the requisite intelligence and monetary support to obtain, for example, a medical degree, perhaps only one-fifth also have the persistence to face continuous study or the temperamental qualities to deal with the emergencies and social demands of such a profession.

Attention to resources of intelligence, particularly in regard to manpower for scientific research, led to application of intelligence tests still more widely in industry and education. Their use in selecting for military promotion and specialized training in World War II was very extensive. In the U.S. systematic surveys of community intelligence were proposed and pursued by J. B. Wolfle, R. L. Thorndike and others, while in Britain the nation-wide systematic guidance of children at 11+ years of age into different educational streams is made about equally on intelligence tests and on school achievement at the time.

Physiological Basis of Intelligence.—This is a complex matter about which only a few basic concepts receive general agreement. From a comparison of differential animal species it has long been evident that intelligence is closely correlated with the size of the cortex or that fraction of the brain which is not directly concerned with internal bodily adjustments, muscular balance, etc. Brain operations on animals show that the decline in problem-solving capacity, as well as in the ability to learn complex habits, is just about proportional to the weight of brain removed. Brain injuries in man point to the same relation. A particular habit or capacity may be lost through injury and may be relearned, but there tends to be a loss in general power of abstraction and problem solving roughly proportional to the extent of cortical damage. In the human brain certain areas appear to be definitely associated with relatively specific bodily functions; *e.g.*, the area at the back of the head with visual perception, other areas with hearing, touch, smell, etc., others again with voluntary movement.

Intelligence, however (in the technical sense), according to most anatomists, is associated with somewhat general structural qualities characterizing the brain cortex as a whole. Thus, microscopic studies of the brains of low-grade defectives show that their nerve cells are comparatively few in number and exhibit comparatively few branches, and both the cells and their branches appear to be arranged far more irregularly than those of the normal person of the same age.

No drug that significantly increases intelligence in normal persons is known. Caffeine in coffee (as well as Benzedrine and related drugs) produces increased problem-solving ability, largely by improving memory and alertness. However, in depressed mental patients such drugs also lead to significant improvements—returns to normal—in general intelligence-test performance.

On the other hand, there are many special physiological influences that will reduce intelligence. Twenty grams of alcohol will produce, in the average person, a measurable decline in intelligence-test performance or other forms of judgment; failure of thyroid secretion produces a considerable decline, as is well known through the history of cretinism; and failures of judgment are rapidly produced by anything that interferes with the supply of oxygen to the brain.

Intelligence in Animals.—The capacity of animals, even of the higher apes, to perceive complex relationships is far below that of adult man and seldom exceeds the level of a three-year-old child, yet it is of the same nature as the intelligence of man. Blind trial-and-error behaviour, the very antithesis of intelligence, is common in animal behaviour. But if animals are presented with sufficiently simple problems, such activity is observed to give way to a thoughtful pause, followed by sudden insight and rise to a new level of adaptive but untaught behaviour. In Köhler's classical experiment a chimpanzee given two hollow sticks, each too short to reach a banana outside the cage, was observed thinking and then fitting one stick into the other to provide a new tool long enough to do the job. Similar switches from random behaviour to "insightful" solutions have been observed experimentally in dogs and even in hens. However, the majority of complex and seemingly very intelligent things that animals do represent either inherited patterns, which go wildly astray anywhere outside the natural environment, or are the result of prolonged, blind, trial-and-error learning, as in most circus animals. Most of their relation-perceiving capacity is concerned with spatial or very simple causal relations, and they conspicuously lack the ability to abstract, generalize and deal with relations between abstractions which makes possible man's use of general symbols in language, mathematics, etc. *See* also ANIMAL BEHAVIOUR; PSYCHOLOGY, COMPARATIVE.

Relation of Intelligence to More Specialized Abilities.—Spencer, in his account of the development of cognitive capacities in the race and the individual, held that the general cognitive capacity which he termed intelligence progressively developed into more specialized abilities. The application of factorial methods to the results obtained with mental tests provided some confirmation of this view. Between 1913 and 1917 a series of investigations among British school children of various ages provided conclusive evidence for certain special abilities (*e.g.*, verbal, numerical, manual and spatial abilities) as well as more formal capacities such as memory and imagination.

Among younger children the general factor of intelligence accounted for the greater part of the individual differences; but with increasing age there appeared increasing specialization, most of the more specific abilities maturing before the end of the pubertal period. In the U.S. a number of researches carried out between 1930 and 1950 by Louis Thurstone and his colleagues threw further light on the number and nature of these more specialized capacities.

The primary abilities (as Thurstone termed them) include what may be labeled as verbal, numerical, spatial, reasoning, perceptual and other capacities of restricted form. A person may develop to a considerable extent in all aspects of one of the forms of ability without equivalent development in the others, though there is also some tendency for all of them to be related as different manifestations of one general intelligence. The causes of these differential developments, whether innate or depending upon interests and environment, are not known.

Intelligence Contrasted With Related Powers.—The reverse procedure from that of predicting adult accomplishment from childhood performance was carried out in Terman's studies of the childhood records of well-known men of genius. These performances, compared with those of living children of known ages, show that children who became geniuses showed intelligence decidedly above their age, though some (*e.g.*, Charles Darwin) did not do well in school. Genius, as the follow-up studies of highly intelligent children show, requires something more than intelligence—perhaps also that touch of madness of which John Dryden wrote ("Great wits are to madness near allied, and thin partitions do their bounds divide"). But intelligence is the first ingredient. Creative imagination has a considerable association with intelligence, though always some indefinable additional power is found at work (*see* CREATIVITY; GIFTED CHILDREN).

On the other hand, though intelligence, as capacity to comprehend, must be analyzed out from the total realm of intellectual performance, it is astonishing to see how many apparently unrelated powers are actually considerably dependent upon intelligence. Though memory can be conceptually separated from

intelligence, goodness of memory (in all but rote, or meaningless, memory) is highly related to goodness of intelligence. The size of the vocabulary, for example, is an excellent indication of intelligence. Again, intelligence operates not only in reasoning but in almost every act of perception, so that the ability to judge where a ball will be in a game of tennis involves intelligence. However, although it is clear from both human and animal psychology that by intelligence is meant the capacity to perceive and handle relationships, and that by higher intelligence is meant capacity to handle more complex relationships, the logician has not yet come to the psychologist's aid by indicating criteria through which the "complexity level" of a relationship, in the hierarchy of relationships, can be independently stated. Until that is done, there is some degree of circularity in the definition of higher intelligence.

INTELLIGENCE, ANIMAL: *see* ANIMAL BEHAVIOUR; PSYCHOLOGY, COMPARATIVE.

INTELLIGENCE, MILITARY AND POLITICAL, the acquiring of information on a national scale, usually about a rival, but sometimes about an ally or a neutral country. Counterintelligence (or security) is the safeguarding of a country's own secrets. Although mainly related to war and to defense measures in peacetime, intelligence and counterintelligence are also concerned with the collection and safeguarding of diplomatic, economic and industrial information. Clearly the acquisition and safeguarding of information are closely associated; in most countries they are both the concern of the same organization.

The effectiveness of counterintelligence measures may often depend on the amount of positive intelligence available; correspondingly, the efficient acquisition of information may hinge on adequate security. Intelligence work involves not only the collection of information, but also its collation and the estimation of its value and reliability, and the making of reasonable deductions from it.

The outstanding examples of intelligence designations in accordance with the general purpose for which the intelligence has been produced are strategic and tactical. Strategic intelligence is designed primarily to satisfy the needs of the strategic planners and policy makers of national governments or very high-level commands.

Tactical intelligence, which is known also as both combat and operational intelligence, is intended chiefly for use by military tactical commanders and units. For example, the broad intelligence which influenced the Allied decision to attempt a major landing on the Normandy peninsula in World War II was strategic; the detailed intelligence used in the preparation of military plans for carrying out this strategic decision was tactical.

Designations of intelligence according to subject matter are numerous and continue to multiply with the increasing division of labour and specialization in large and complex intelligence organizations, especially at the government or strategic level. For example, military intelligence, which was once the comprehensive term for all intelligence relating to military matters, has been partially superseded in practice by army, air and naval intelligence. Each of the latter three, in turn, has been broken up into several fields of intelligence specialization. Order-of-battle intelligence, for instance, deals largely with the organization, strength, disposition, weapons, equipment, logistics, training and tactics of armed forces.

Geographic intelligence, the comprehensive term for land, sea and air data required for military plans and operations, includes several subdivisions of major importance, such as topographic, hydrographic, weather and meteorological intelligence. Transportation intelligence, which was once an integral part of geographic intelligence, has itself become a separate major field. Tremendous advances in the weapons and equipment of warfare have led to the emergence of technical intelligence as a field of vital importance to national security everywhere. Part and parcel of technical intelligence is scientific intelligence, which has brought forth its own progeny of intelligence specializations on nuclear fission, electronics, guided missiles, telecommunications and chemical and biological warfare.

The fields of political, economic and sociological intelligence have come to be regarded as having great importance for a nation's armed forces as well as for its foreign service. Military scientists are in general agreement that the military planner and policy maker must know the governmental structure, the political groupings, the national policies and objectives, the industrial complex and the social matrix of a potential enemy. Moreover, commanders of forces operating in foreign countries must be similarly informed if they are to deal effectively with guerrilla and resistance activities, satisfactorily administer local government on a wartime basis and conduct a sound psychological program. The fact that the Nazis either did not have or did not use adequate political, economic and sociological intelligence on the Soviet Union has often been cited as a significant factor in the failure of the World War II invasion of the U.S.S.R. by Germany.

Historical.—From earliest times, rulers and governments have attempted to acquire information about rival countries, and rival armies about their opponents and about the topography and other matters in a probable theatre of military operations. Local military information during a campaign, or before battle, was sometimes obtained from local inhabitants, but more often by means of cavalry patrols, while long-term information was obtained through agents (or spies), traitors and casual travelers.

Indeed, the history of intelligence, as distinct from military reconnaissance in the field, is very largely the story of agents and spies. To define a spy precisely is difficult and the word has slightly different meanings according to the country and conditions. A man seeking information while dressed in military uniform is generally considered not to be a spy or an agent but a scout who, if apprehended, is entitled to treatment as a prisoner of war. On the other hand, one whose role is to obtain secret information, by clandestine methods while dressed as a civilian, is an agent or spy and in most countries is liable to the death penalty if caught.

Further, an individual may be a traitor as well as a spy or an agent if he works for a foreign country against his own. Difficulties arise in interpreting these definitions in the case of irregular forces who do not wear proper or easily recognizable uniforms and with revolutionary forces. (*See* ESPIONAGE; PRISONERS OF WAR.)

From the middle ages to the late Renaissance diplomacy and intelligence were so closely bound together that foreign ambassadors were sometimes regarded as little better than spies. In particular, the Venetian republic established embassies and missions abroad and made a point of obtaining what would now be considered remarkably full intelligence reports from its ambassadors and agents. In England espionage was a serious business by Elizabeth I's reign, when an elaborate intelligence system was organized by Sir Francis Walsingham (*q.v.*) in order to obtain information from the continent, mainly from Spain. So great was Walsingham's enthusiasm for intelligence work that, in the absence of public funds, he devoted almost the whole of his considerable private fortune to furthering it.

More than a century later, in the reign of Queen Anne, the chief organizer of British intelligence was Daniel Defoe, who may be said to have been the founder of the modern British secret service —a role in which the author of *Robinson Crusoe* is not familiarly known.

Espionage flourished in the Napoleonic Wars and it is difficult to select individuals for special mention. Perhaps Napoleon's great intelligence organizers, Joseph Fouché and René Savary (duc de Rovigo), were the best known and most successful. Much of Napoleon's military success was a result of the diligence with

which his famous chief of staff, Marshal Louis Alexandre Berthier, collected information in the field.

Until several years after the Napoleonic Wars intelligence activities were greatly restricted by the limitations of communications. The horse was in those times the swiftest means of travel on land and the sailing ship by sea. These were also the quickest agencies for passing information, with the exception of the carrier pigeon—popularly believed to have been used to convey the result of the battle of Waterloo to Nathan Mayer Rothschild in London. This means, however, was not practised extensively or properly understood until later, by which time it had been superseded by telegraphy.

The limitations of the times were naturally less hindrance to the collection of long-term, or strategic, information than to that of tactical or battle intelligence. Rival navies were nearly always completely in the dark about each others' movements, the first warning of the approach of an enemy squadron invariably being given by the lookout in the crow's-nest of a scouting frigate only a few miles ahead of the main fleet. On land, comparatively large armies could bivouac or maneuver within a few miles of each other in mutual ignorance. In spite of his considerable force of cavalry Napoleon was unaware of the direction of the withdrawal of Marshal Blücher's Prussian army after Ligny and Quatre-Bras and was largely surprised when it reappeared on the battlefield of Waterloo 48 hours later.

Developments Since the Mid-19th Century.—The latter half of the 19th century saw revolutionary changes in means of transport and so of passing information. Railways, the steamship, the submarine cable and the telephone, and the internal-combustion engine all played their part. Together with developments in other fields, these increased the tempo of diplomacy. Under these conditions a good intelligence service paid large dividends and in consequence the great powers tended to maintain intelligence organizations of ever-increasing size and efficiency. The 20th century was to witness the introduction and rapid development of aircraft and the universal use of wireless telegraphy—two inventions which further increased the potentialities of a good intelligence system.

Apart from new scientific aids, the general conditions of World War I favoured intelligence activities in neutral countries. In western Europe—the main theatre of war—the rival armies faced each other in static positions at close quarters for four years, on a front extending from the English channel to Switzerland. This line of battle was flanked by neutral countries—the Netherlands and the Scandinavian countries to the north and Switzerland to the south—where spies and agents of both sides could work in comparative safety. British intelligence earned a deservedly high reputation during the years 1914–18. Two of its earliest successes were the immediate and unobtrusive arrest on the outbreak of war of practically all enemy agents in the United Kingdom, and the acquisition of the German naval cipher, which, for some time, gave the British admiralty prior notice of all major movements by the enemy fleet. M.I.5 became a legendary organization and, it must be confessed, often got credit which was properly due to other agencies.

World War I produced many agents who worked in neutral countries as well as from belligerents. Among the best known was the German Kapitän Franz von Rintelen who was sent to the United States in 1915 to sabotage American aid to the Allies. The security measures in neutral America at that time were lax, as the United States had up to then escaped the intensive espionage activity which Europe had experienced for centuries. In consequence von Rintelen had considerable success, until U.S. entry into the war in April 1917 put an end to his activities. Perhaps the most publicized spy of all time was the Dutch-born agent known as Mata Hari (born Margaret Gertrude Zelle) who operated in Paris, Rome, Vienna, Berlin and other continental cities, from 1905 until her execution as a spy in France in Oct. 1917.

Long before the outbreak of World War II in 1939 intelligence and counterintelligence had ceased to be solely concerned with diplomatic and military secrets; it became one of the main duties of a national intelligence service to uncover industrial and scientific data on which the war potential of its enemies, or likely enemies, increasingly relied.

After the end of hostilities in 1945 "cold warfare" conditions, and the development of nuclear weapons, further extended the scope of the work of the intelligence organizer as well as of its urgency. There was hardly a field of human activity which was not liable to be probed by the intelligence agent, or which had not taken on a security aspect.

The methods of obtaining intelligence have been largely misrepresented by fiction writers and film producers. In popular estimation intelligence is usually associated with the glamorous spy, disguise, forged passports and clandestine meetings. It is untrue to say that these methods are never employed, but they are the exception rather than the rule. A very considerable part of all useful intelligence is gained by routine methods: from the press, through travelers, businessmen and others who may pick up something in the course of their normal work; by piecing together a number of apparently trivial facts which in isolation are worthless, but together may be of considerable value. The professional agent or spy is, generally speaking, sparingly employed, or reserved for missions of special urgency. Most of those who provide information are casual agents with no professional status in the intelligence world.

The so-called international spy is, however, worthy of mention. Mostly men, but sometimes women, they may be said to be products of the 20th century. Invariably persons with little or no national loyalties, they are often of mixed race, frequently with a grievance against their own country. Many have criminal records. Their information is rarely of much value; they work for the highest bidder, but are quite prepared to double-cross their first employer if they find a better one. Nevertheless, they flourished in considerable numbers in the period between World Wars I and II. Paris, Brussels, Geneva, Cairo and other cities where communications meet and international affairs are conducted, were their clearinghouses. They were thoroughly unreliable, and their haunts were usually well known to the police and security agencies. Yet, a few of them seem to have had some success, and even standing, in the intelligence world, as was revealed by a number of arrests and trials in the 1930s.

Intelligence in World War II.—By reason of the development of scientific equipment, and the world-wide and fluid nature of military operations, intelligence during 1939–45 reached a high pitch of activity and efficiency. In most theatres of land operations there was no continuous and heavily manned front line; sometimes the belligerents became inextricably mixed. The number of different nationalities involved and the frequent difficulty of distinguishing friend from foe made the work of the agent and military intelligence personnel profitable in countries such as Belgium and France (1939–40 and 1944–45), Norway (1940), the middle east, Burma and Malaya. Conversely, counterintelligence was much more difficult.

The means of gathering information was greatly increased by scientific developments. Aircraft, and particularly photographic reconnaissance, made it possible to unmask installations and troop dispositions in both the strategic and tactical fields. Wireless interception and ability to "break" mechanically even the most intricate cipher or code, made the acquisition of information by this means a regular feature of intelligence procedure.

In this connection it should be noted that the United States' intelligence successfully broke the Japanese cipher before Pearl Harbor. This enabled the United States government to have prior information of Japan's generally hostile intentions, although it did not give early warning of the actual time, place or manner of attack. *See* CRYPTOLOGY.

Deception was practised to a greater extent than ever before. Every plan of operations was masked by a skilfully prepared "cover plan"—in other words a bogus plan which the enemy was intended to discover and to regard as the real plan. Before the battle of El Alamein in Oct. 1942 a concentration of troops was simulated by means of dummy tanks, vehicles, camps and water points. Before the landings of U.S. and British troops in Normandy in June 1944 a most elaborate cover plan was designed

with the object of giving the Germans the impression that a landing in the Pas-de-Calais was contemplated. Large camps and vehicle parks were established in Kent and Essex, and bogus wireless traffic was maintained in order to direct attention toward the Dover and Calais areas and away from Normandy. A possible landing in Norway from the east coast of Scotland was also simulated on the wireless.

The older intelligence methods were greatly extended in World War II. Elaborate Allied espionage systems were organized in Norway, Denmark, the Netherlands, Belgium, France, Greece, Burma, Malaya and other occupied territories. Contact was maintained by means of clandestine wireless sets and personnel dropped by parachute or landed from submarines or small craft. (In Japan a most successful spy was the German press correspondent Richard Sorge, who was a member of the Nazi party but nevertheless a convinced Communist and a Soviet spy.)

Intelligence in the Cold War.—After 1945 many new factors arose which affected intelligence work. International frontiers were redrawn; countries with centuries of independence became satellites of the U.S.S.R.; colonial and protected countries gained full independence. As an outcome of these great changes many thousands of persons became displaced and stateless and many others left their old homelands and sought sanctuary elsewhere. These conditions made infiltration by agents, and the path of the spy, comparatively easy. In addition, the division of most of the world into two sharply defined blocs—eastern Communism and western democracy—produced subversive elements of a new type. Educated men and women holding responsible positions in the west had, for what they believed to be idealistic motives, defected to Communism. Conversely, individuals from Communist countries sought and obtained political asylum in the west.

In Sept. 1945 Igor Gouzenko, an official in the Soviet embassy in Ottawa, defected to Canada and thereby uncovered the activities of Klaus Fuchs and Alan Nunn May who were employed in Britain in nuclear research work of the greatest secrecy. The extent to which these two men's subversive activities helped the U.S.S.R. is difficult to judge, but they may have assisted Russia considerably in developing the atom bomb, and thereby hastened the end of the British-U.S. monopoly.

At that time Bruno Pontecorvo was also employed in Canada on atomic research. In 1950 he disappeared from Helsinki, Fin., and went to the U.S.S.R., where he remained.

In 1954 a Soviet agent, Vladimir Petrov, and his wife, who were both employed at the Soviet embassy in Australia, dissociated themselves from the U.S.S.R. and were given political asylum by the Australian government. This disclosed a vast network of Soviet espionage in Australia. Not all these individuals were professional agents. With some their defection was due to genuine, if misguided, ideological beliefs.

The number of defections from one ideology to another in the years after World War II was greatest from east to west. In Berlin alone tens of thousands crossed permanently from the eastern to the western sectors each year, whereas the numbers in the opposite direction were small. Only a very few were spies; but some were, and it demonstrated the ease with which agents could be transferred to the west from eastern Europe. Nor was Berlin the only place. Similar facilities existed in many parts of Europe where east-west frontiers were contiguous, and in many parts of the world outside Europe; *e.g.*, Hong Kong. After 1945 the opportunities for "planting" agents in research establishments, service units, government offices, docks and factories increased.

As a consequence of such conditions the security side of intelligence developed and expanded in all national intelligence organizations. Security in Great Britain was clearly easier than in most countries. Its position as an island made it possible to impose strict control over entry and exit, and its population was unusually homogeneous. This reduced the number of likely traitors and the chances of subversive activities. States with land frontiers with other countries had a much more difficult security problem. The U.S.S.R. had the additional anxiety of satellite states and a large non-Russian population of doubtful loyalty. Although otherwise favourably placed from the security point of view, the United States had a less homogeneous population than Great Britain and this is reflected in the very elaborate security organization which it maintained.

The Korean War (1950–53).—This conflict provided unique opportunities to both sides for the acquisition of tactical information. After the first few weeks, when operations had stabilized, it was very difficult for either side to make a tactical move of any significance without its opponents receiving prior warning. This was due very largely to the fact that North Koreans and South Koreans are of the same race, speak the same language and dress in a similar manner. This made the task of the native intelligence agent a relatively easy one.

Conversely, the task of those responsible for tactical security was more difficult. On the other hand, it was probably more difficult for both sides to gain useful strategic information than is customary in modern war—due to the North Korean and Chinese "volunteer" forces possessing practically no aircraft, and the strategic reconnaissance of UN aircraft being confined, for political reasons, to areas south of the Yalu river. In this connection it should be noted that the original attack by North Korea on the Republic of Korea (South Korea) in June 1950 was to a very large extent a surprise, as was the participation of Chinese troops in Oct. 1950.

Modern National Intelligence Organizations.—The general pattern of intelligence systems in all countries is very similar. In all there is a higher directing organization in the home capital which deals with political, economic and industrial intelligence, security policy and, where necessary, co-ordinates intelligence work in the separate fighting services. Intelligence organizations are represented abroad at embassies, consulates and vice-consulates. Within the fighting forces intelligence is organized, collected and sifted by the service intelligence staffs.

Although the general organization and methods of collecting information are common to most countries, there is a marked difference in security, or counterintelligence, methods. In most democracies the conduct of security measures is somewhat limited by the need to proceed according to ordinary law, which is applicable to military and police personnel engaged in security duties in the same way as to other citizens. In many other countries the secret police, who are responsible for security, have exceptional powers of arrest, detention and interrogation.

It is one of the chief duties of the security side of a national intelligence organization to safeguard the system and methods by which it operates. It is, therefore, not surprising that detailed information concerning the organization of intelligence in various countries is scanty. The following notes give in outline the organization in the four major countries: the United States, Great Britain, France and the U.S.S.R.

United States.—The United States has shown great generosity and understanding in giving asylum, and a home, to large numbers of political refugees and stateless persons from Europe. Since 1945 this liberal immigration policy, although it has served the country well, has placed emphasis on the security side of intelligence, since among so many foreigners, without inborn loyalty to the United States, some were almost certainly spies. The three fighting services have their own intelligence services; in addition there are many other agencies which deal with various aspects of intelligence. All intelligence is controlled by the Central Intelligence agency (CIA), which was established in 1947 to work under the National Security council. The functions of the agency are: (1) to advise the National Security council on security matters; (2) to co-ordinate all departments and agencies in relation to intelligence; (3) to correlate, evaluate and distribute intelligence information to the appropriate agencies; (4) to deal with certain matters common to all intelligence agencies; (5) to perform such other intelligence functions as the National Security council may direct.

A body known as the Operations Coordinating board is also concerned with the security side of intelligence. The director of the CIA is a member of this board, the purpose of which is to provide for the integrated implementation of national security policies by the many agencies involved.

Great Britain.—The central organization for British intelligence is the Joint Intelligence bureau which is responsible for: (1) coordinating intelligence in the three fighting services; (2) intelligence work common to all three fighting services; (3) economic and scientific intelligence; (4) intelligence relating to guided missiles and other new weapons.

Each fighting service has its own intelligence organization. Those of the Royal Navy and Royal Air Force are mostly concerned with technical matters; that of the army is of a more general nature and on a larger scale. Before the formation of the Joint Intelligence bureau after World War II, military (*i.e.*, army) intelligence was the agency mainly responsible for many items of general intelligence now within the province of the Joint Intelligence bureau.

The acquisition of intelligence overseas is to a considerable extent the responsibility of the service intelligence organizations, mainly the army. Counterintelligence at home is vested in a number of agencies. Those primarily responsible are the Joint Intelligence bureau and the three service intelligence organizations, but the civil police, through the home office, are also closely concerned. The personnel of intelligence agencies have no powers of arrest, detention or interrogation. The general procedure is that the intelligence agencies provide the information, while Scotland Yard and the various city and county police forces act on the information. Sometimes the civil police in their normal anticrime work unearth espionage activities. The special security agencies and the civil police work in close co-operation.

France.—Each of three fighting services has its own intelligence department, known as the *deuxième bureau,* which deals with various aspects of intelligence. These three service *bureaux* are linked to the headquarters of the *deuxième bureau* at the ministry of defense. All security matters (including counterespionage) are dealt with by *S.D.E.C.E.* (Service de Documentation Extérieure et de Contre-Espionnage) and *D.S.T.* (Direction de la Surveillance du Territoire). Each ministerial department is responsible for its own security. Security within the armed forces and services is the responsibility of the *securité militaire.* As in Great Britain all security agencies work in close co-operation with the civil police.

U.S.S.R.—Before the 1917 Revolution Russian intelligence was primitive and inefficient; security was confined largely to the investigation of movements and plots against the regime. After the early 1930s a highly efficient Soviet intelligence and counterintelligence system spread its net over every phase of national life and over activities of the U.S.S.R. in foreign lands. At the beginning of the 1960s, under the direction of the State Security committee, there were two main branches of the organization, located within the U.S.S.R.: the G.R.U. or chief intelligence directorate of the Soviet army and the intelligence unit within the secretariat of the Communist Party of the Soviet Union which is responsible for furthering Communism in foreign countries. Each of these branches handles a variety of intelligence and security matters in foreign countries, but there is much overlapping and many of the subject headings fall outside the term "intelligence" as known in non-Communist countries.

The following are among these activities: sabotage; political and military intelligence sections (including secret intelligence groups) organized by Soviet embassies in foreign capitals; guerrilla movements (actual and potential); spy groups and intelligence agents; and agitation and propaganda for the Communist parties. Contrary to the custom with most countries, where intelligence is in the hands of specialists, it can be said that every Soviet citizen in a foreign country is in some degree a Communist agent or an agent for some branch of the intelligence system of the U.S.S.R.

International Intelligence.—NATO has no intelligence organization of its own, but relies on those maintained by its member countries. The signatories of the Warsaw treaty are believed to rely very largely on the Soviet intelligence system which is known to operate extensively in the satellite countries.

INTELLIGENCE TEST: *see* PSYCHOLOGICAL TESTS AND MEASUREMENTS; INTELLIGENCE; DIFFERENTIAL PSYCHOLOGY.

INTENDANT, a commissary of the king under the *ancien régime* in France. The institution was both the instrument of crown centralization and the focus of provincial life. Its origin, however, remains obscure, because of the complexity of the circumstances to be taken into account and the absence of any document specifically creating it. When "intendants of justice, police and finances" are found mentioned in 1625, this title in fact covers functions which were being exercised long before that date by men who enjoyed the king's confidence; and it was not until the reign of Louis XIV that the intendants received their full status.

The institution had its beginnings in the crown's obligation to recover the authority which it had alienated through the sale of offices. This it did by placing, over the royal officials who by purchase had become the proprietors of their offices, agents with well-defined powers under *lettres de commission* for a certain length of time. It was thus that Francis I in 1526 appointed some *maitres des requêtes de l'hôtel* ("masters of requests of the household") to be sent on tours of the provinces. In 1551 these agents were given the title of *commissaires départis pour l'exécution des ordres du roi* ("commissaries sent out to execute the king's orders"); and a decisive step was taken in May 1555 when Henry II gave to each of his *maîtres des requêtes* in the provinces a particular sphere of action or *généralité.* Special commissaries were also dispatched to particularly troubled areas, to an army in the field or to a provincial governor, with the title of "intendant of justice" or "intendant to the army." The word "intendant" as yet meant no more than supervisor, so that the sphere of supervision always had to be exactly defined. Intendants to the army appeared in 1555 in Touraine, at Lyons and in Corsica. It was at Lyons that intendants of justice were first made permanent, notably from 1601 to 1607; before that their task had been essentially to apply edicts of pacification after civil war, in which capacity they were called *commissaires de l'édit.*

The cardinal duc de Richelieu made systematic use of institutions which had been established long before his time but which had been used only as occasion required. Richelieu, who recommends the use of intendants in his *Testament politique,* himself increased the number of commissaries sent on provincial tours or on missions of inquiry to provincial governors; but he never gave to these envoys power to make decisions. Inevitably these *commissaires départis* (as they were then generally called) became the rivals of the local authorities, particularly of the treasurers general of the *bureau des finances* functioning in each *généralité.* The commissaries' authority was extraordinarily enhanced by a ruling of Aug. 22, 1642, which associated them with the *bureaux des finances* to help with the apportioning of the *taille.* This growing power so much disquieted the local governors and officials that in the declaration of July 11, 1648, inspired by Mazarin, Louis XIV revoked the powers of all the intendants except those in certain frontier provinces; but this decision, taken when the Fronde was breaking out, had no lasting effect, and "intendants of justice, police and finance" were re-established by Mazarin at the beginning of 1653.

From the start of his personal government (1661), Louis XIV maintained the intendants, who thenceforth became the regular

representatives of royal power. An intendant was appointed to each *généralité* except Toulouse and Montpellier, which were combined under the intendant of Languedoc, so that there were 33 intendants for the 34 *généralités* in 1789. Appointed by the king, who could likewise recall him when he wished, the intendant received *lettres de commission* which laid down his duties and which he deliberately refrained from having registered at the local sovereign courts for fear of losing his liberty of action. Intendants were recruited particularly from among the *maîtres des requêtes* and the *noblesse de robe* or judicial nobility. Moved readily from one *généralité* to another under Louis XIV, they tended to fix themselves during the 18th century, though this did not prevent them on occasion from living in Paris. They handed over their duties to subordinates or *subdélégués*. These men, chosen at first personally by the intendants, were made royal officers in 1704. There were several *subdélégués* in each *généralité*. An intendant could also have a council, often called the *conseil d'avocats*, for consultation in difficult cases.

The authority of the intendants extended into every sphere of the administration: indeed the use of the latter term in its modern sense grew up with them, since they were the forerunners of the change from the judicial magistrature as exercised by *parlements* or by *bureaux des finances* to the administrative magistrature as exercised by prefects. As *commissaires départis*, they were responsible for carrying out the central power's orders in their *généralités*, supervising the local officials, representing the crown at the local autonomous bodies (provincial estates in particular) and informing the central power about the economic situation and public opinion in their *généralité*. From this point of view their correspondence with the *contrôleur général des finances* and the *mémoires* which they kept up to date from the end of the 17th century are particularly valuable. Their mission remained always one of providing information rather than of making decisions, and in order to act they had to obtain an order from the king's council, which however would often be drafted on the lines that they suggested. As intendants of justice they could preside over local courts, suspend unsatisfactory magistrates and install extraordinary tribunals to suppress brigandage and sedition. As intendants of finance, they determined the incidence of the *taille* (*q.v.*) in the *pays d'élection* and discussed with the assemblies the amount of the annual tax to be voted in the *pays d'états*, and it was their responsibility to collect the new taxes levied at the end of the 17th century. It was, however, as intendants of police that they played their most important role. Responsible for public order, they co-ordinated the activities of the *prévôts des maréchaux* (the police force under the marshals of France) and sometimes intervened in the affairs of private persons, prompting the dispatch of *lettre de cachet* (*q.v.*). They likewise controlled municipal administration, and it is to them that many provincial towns owe their magnificent squares. In road building, Daniel Charles Trudaine, intendant of Auvergne from 1730 to 1734, was especially distinguished.

Enlightened administrators in the century of the Enlightenment, the intendants were champions of the physiocratic school (*q.v.*) and also of the use of statistics: the baron de Montyon (Antoine Auget), intendant of Auvergne from 1768 to 1773 and Provence from 1773 to 1775, wrote under the pseudonym of M. Moheau the first reasoned demographic treatise, *Recherches et considérations sur la population de la France*, two volumes (1778). Yet their omnipotence and their omnipresence made them unpopular, and it was partly to remedy their excess of power that the so-called *assemblées provinciales*, with consultative and administrative powers, were set up throughout France in 1787. The powers of intendants were suppressed by the Constituent Assembly on Dec. 22, 1789.

INTER-ALLIED DEBTS: *see* WAR DEBT.

INTER CAETERA, a papal bull of May 4, 1493, defining areas of sovereignty over newly discovered lands, was issued by Alexander VI after reports of the first voyage of Christopher Columbus reached the pope and the Spanish and Portuguese rulers.

Under this bull and one of May 3, a line of demarcation was drawn 100 leagues west of "the islands commonly known as the Azores and Cape Verde," and the rulers of Castile and León were confirmed as the sovereign power over all lands already discovered or to be discovered west of that line which were not "in the actual possession of any Christian king or prince."

Portugal, which held colonies along the coast of Africa, was to retain its rights and privileges east of the line. In September of the same year, the pope expressly confirmed in another bull the Spanish rulers' right to hold lands to the "eastern region and to India."

Under the treaty of Tordesillas, June 7, 1494, the Spanish crown agreed to move the line of demarcation 370 leagues west from the Cape Verde Islands, thus giving Portugal a claim to Brazil.

INTERCOLUMNIATION, in architecture, the distance between the columns (*q.v.*) of a colonnade; usually defined by the number of times in which the bottom diameter of the column is included in the distance between the two closest points on adjacent columns. Thus the distance between the centre lines of two columns is one diameter more than their intercolumniation. The intercolumniation of classic columns was systematized at an early date, and the following standard intercolumniations have been listed by Vitruvius and others: (1) pycnostyle, equal to $1\frac{1}{2}$ diameters; (2) systyle, 2 diameters; (3) eustyle, $2\frac{1}{4}$ diameters, so-called "well-columned," as the one most generally satisfactory; (4) diastyle, 3 diameters; (5) areostyle, 4 diameters; and (6) areosystyle, a complex form in which the columns are arranged in pairs with the distance between the pairs greater than the distance between the columns of each pair, as in the colonnade of the Louvre, Paris (by Claude Perrault, 1665). No such absolute standardization of intercolumniation as Vitruvius' list would suggest exists in classical work; frequently all the intercolumniations of a single colonnade differed, with the widest in the centre. The list must therefore be considered, like the so-called rules for the orders, merely as a summary of the averages. *See* ORDER.

INTEREST is the price paid for the use of credit or money. The term is used to denote either a payment expressed in money ($8 per $100 per year, or similarly in other currencies) or the rate of payment (8% per year).

Measured in money, interest is the difference between the total that is repaid and the sum originally advanced, which is known as the principal. If, for example, $100 is borrowed for three years and the borrower pays the lender $112 at the end of the third year, the interest is $12. The rate of interest is the ratio between the amount of interest earned during a unit of time and a unit of principal. In interest computations, a rate is expressed as a decimal. Thus 8% (which really means $\frac{8}{100}$) is written as .08. The traditional unit of time in finance is one year, but by agreement some other period of time, such as a month or day, may be used.

Interest charges vary in amount directly with time: the longer the period that the principal is in use the more interest must be paid. Similarly, interest varies with the principal and the rate. The mathematical relationship between these components of any interest problem is expressed in the familiar formula: $I = P\,r\,t$. In this formula, I represents the total interest paid in money; P represents the principal, the amount of money borrowed; r represents the rate of interest expressed as a decimal; and t represents the time covered by the transaction, expressed in the agreed upon units of time. If any three of the four components are known, the

fourth can be computed by the formula. For example, if $350 is borrowed for three years at the rate of 5% per year, the formula will read as follows:

$$I = \$350 \times .05 \times 3$$
$$I = \$52.50$$

Another important use of the formula is to calculate the rate of interest in a given transaction. Using the same example given above, the problem may be stated as follows: What is the rate of interest when $350 earns $52.50 in three years? To solve this problem, the formula is written thus: $r = \frac{I}{pt}$. Substituting the given values, the problem is solved as follows:

$$r = \frac{52.50}{350 \times 3} = \frac{52.50}{1050} = .05 = 5\%$$

For periods less than one year, time is measured in days, and the time element in the formula is expressed as a fraction of a year. For example, if money is borrowed for 30 days, t in the formula becomes $\frac{30}{365}$ (or in leap year $\frac{30}{366}$). Interest so computed is called exact interest. For ease in computation it is customary in commerce and banking to use 360 days instead of 365 in the denominator. Interest so computed is called ordinary interest and is always slightly more than exact interest.

Interest may be paid in one of three ways: (1) all paid at the very beginning of the contract; (2) all paid at the very end of the contract; (3) paid in part at different times as the contract progresses.

When all the interest is paid at the beginning of the contract, the interest charge is called discount. The borrower who applies for a loan of $100 for one year at an interest rate of 5% a year receives only $95 in cash but pays back $100 at the end of the year.

Interest paid according to (2) is called simple interest. It is computed only once, at the end of the contract, for the entire elapsed time. All results are computed by the formula

$$I = P\,r\,t.$$

Interest paid according to (3) becomes compound interest. This type involves interest paid on interest, because as interest is received periodically it is added to the existing principal to form a new principal. This enlarged principal earns more money in the subsequent period, though the rate remains the same. The following example illustrates the method of computing the compound amount when $100 gathers interest for three years at a rate of 4% per year:

Starting principal	$100.00
Interest at 4% the first year	4.00
Amount at end of first year	104.00
Principal at start of second year	104.00
Interest at 4% for second year	4.16
Amount at end of second year	108.16
Principal at start of third year	108.16
Interest at 4% for third year	4.33
Amount at end of third year	112.49

At simple interest the amount at the end of the third year would be $112.00. For periods of more than one year compound interest is always more rewarding than the corresponding simple interest, and for long periods of time the advantage becomes substantial.

To distinguish compound interest from simple interest it is customary to use n for the units of time and s for the sum of principal and interest.

The formula for determining the compound amount is usually written as $S = P(1 + r)^n$.

The amount of compound interest, as distinguished from the compound amount, is determined by subtracting the original principal from the compound amount. For large values of n the computation of $(1 + r)^n$ is tedious and time consuming. Standard tables of such computations are available for many values of r and n.

Instead of annual compounding, interest is often compounded at fractional periods of a year. Banks, for example, frequently pay interest quarterly on savings accounts. If the quoted interest rate is 4% compounded quarterly, interest is earned at the rate of 1% each quarter. On $100 the compound amount at the end of each quarter (to four decimal places) would be successively $101.0000, $102.0100, $103.0301 and $104.0604. The standard tables carry such computations to eight or more decimal places.

By simple interest the $100 on deposit would earn $4 in interest by the end of the year. By compounding quarterly the same principal would earn $4.06. In such transactions the quoted rate is called a nominal interest rate. The rate actually earned is called an effective rate and is designated by i. In this example $i = 4.0604\%$.

The formula $S = P(1 + r)^n$ can be used to compute the effective rate, but r must be the rate per conversion period (when interest is credited and becomes part of the principal) and n must be the total number of conversion periods in the whole transaction. The following example illustrates the method: If $400 is invested at 6% (per year), compounded quarterly for 20 years, the formula becomes $S = 400(1.015)^{80}$, because 1.5% is earned each quarter and there are 80 quarterly conversion periods in 20 years.

In time payment plans, so popular and useful in consumer buying or borrowing, the amount of principal of which the consumer has use reduces as each payment is made. These partial payments of principal introduce new difficulties in rate computation. The true interest rate in installment plans can be computed accurately by annuity formulas, but such computations require special training and access to tables. There is available, however, the so-called constant ratio formula, $i = \frac{2ml}{P(n + 1)}$, which requires no tables and no special mathematical skill. This formula gives an approximate result that is close enough to the effective rate for most practical purposes. In this formula m is the number of payment periods within one year (12 for monthly payments, 4 for quarterly payments) and n is the total number of payment periods in the contract. The following example illustrates the procedure: A loan of $100 is to be repaid in 12 equal monthly payments at a charge of 7% discount. What is the effective interest rate? In this case, P is $93, I is $7, m is 12 and n is 12. The constant ratio formula works out as follows:

$$i = \frac{2 \times 12 \times 7}{93\ (12 + 1)} = \frac{168}{93 \times 13} = \frac{168}{1209} = 13.895\% \text{ or } 13.9\%$$

By the more accurate annuity method, i equals 13.6%. *See* also CAPITAL AND INTEREST and references under "Interest" in the Index.

INTERFERENCE OF LIGHT: *see* LIGHT: *Waves and Interference;* INTERFEROMETER.

INTERFEROMETER. An interferometer is an instrument which makes use of the interference of waves for the purpose of measurement. After an introduction which includes a classification of interference effects, this article is divided into the following sections:

I. Interferometers Using Division of Wave Front
  1. The Väisälä Interferometer
  2. Michelson's Stellar Interferometer
II. Interferometers Using Division of Amplitude
  1. Fizeau-Laurent Surface Interferometer
  2. The Jamin Interferometer
  3. The Michelson Interferometer
  4. The Twyman-Green Interferometer
  5. The Linnik Interference Microscope
  6. The Mach-Zehnder Interferometer
  7. The Bates Wave-Front Shearing Interferometer
  8. The Fabry-Pérot Interferometer
  9. The Echelon and Lummer Plate Interferometers
III. Multiple-Beam Interferometry
  Some Applications of Multiple-Beam Interferometry

Interferometers are most commonly adapted for use with sound or light waves. For a discussion of acoustic interferometry *see* SOUND: *Applications of Sound.*

This article will be devoted entirely to optical interferometers,

which can be conveniently divided into two broad groups. In the first, metrical interferometers, light waves of known wave length are used for the measurement of metrical or optical lengths. In the second group, interference spectroscopes, the objects under study are the light waves themselves (*see* SPECTROSCOPY). Because the wave length of visible light is only of the order of $\frac{1}{2,000}$ of a millimetre, metrical interferometers can only be used for the evaluation of quite small differences in length; nevertheless it is possible to compare large lengths provided they only differ by small amounts. Thus it becomes convenient to subdivide metrical interferometers into those used for measuring quite small lengths and those which can be used for the evaluation of lengths up to as much as 100 m.

Although the existence of phenomena caused by optical interference was known to Robert Boyle, Robert Hooke and Sir Isaac Newton as early as about 1665, it was not until 1802 that the fundamental mechanism was clarified by Thomas Young, who was the first to enunciate the theory that optical interference involves the principle of coherence and the principle of superposition (*see* LIGHT). The essential features are (1) that light beams from two independent sources, being incoherent, can only combine their intensities; but (2) light beams from any one point of a source, which may have traveled over different paths and then come together again, being coherent, can combine their amplitudes, and this can lead to stationary fluctuations of intensity in space, called interference fringes. An interferometer is essentially an optical system that divides a beam of light from a source into two (or more) beams which follow different paths and then are recombined. If there are differences in either the optical or metric paths, then each wave-length difference leads to a shift of one interference fringe. Thus small differences become measurable.

Varieties of interference fringes were discovered successively during the first half of the 19th century by Young, A. J. Fresnel, Sir John Herschel, Sir David Brewster, Humphrey Lloyd, W. K. von Haidinger, W. H. F. Talbot, F. Billet and others. They were treated as academic curiosities until J. C. Jamin in 1856 invented his celebrated interference type of refractometer (*q.v.*), followed in 1859 by A. H. Fizeau who carried out an ingenious interferometric test of the water-velocity-drift formula proposed by Fresnel. Then in 1862 Fizeau applied thin-film fringes to the measurement of the thermal expansions of small bodies. Following Fizeau there were many developments, leading to a great expansion of interest in the subject by the mid-20th century and increasing use of interferometers for precise physical measurement.

Classification of Interference Effects.—Interference phenomena can be conveniently classified according to (1) chromatism; (2) wave division; (3) fringe localization; (4) multiplicity.

1. Some interference phenomena can be produced with white light; others require an approximately monochromatic source. The line width (departure from true monochromaticity) imposes restrictive limitations in many interference experiments.

2. The condition of coherence requires the division of the wave front into separate beams. This can be done either by (a) division of the wave front by slits or apertures or (b) division of the amplitude of a wave front by the double act of partial reflection and partial transmission at a reflecting interface.

3. Fringes, according to their mode of origin, may be non-localized (*i.e.*, extend into space), localized on a surface or appear at infinity.

4. While many interference systems use two interfering light beams (two-beam interference) others use many geometrically related beams (multiple-beam interference). Correct use of multiple beams leads to a considerable reduction in the widths of the interference fringes and thus to an increase in sensitivity and accuracy.

I. INTERFEROMETERS USING DIVISION OF WAVE FRONT

In such instruments a coherent wave front is divided, usually by two parallel slits or by two separated mirrors. The Rayleigh interference refractometer, described in 1896 (*see* REFRACTOMETER), incorporating the modern improvements of F. Haber and F. Löwe (1910), is widely used for the determination of the refractive indices of gases and liquids. A diagram is shown in fig. 1.

Fig. 1(A) shows a plan view and fig. 1(B) an elevation view. From a slit source S, light rendered parallel by the lens L_1 falls on two fairly wide slits 1 cm. apart (S_1S_2). After passing through the tubes T_1T_2 and a compensating device G_1G_2 (invented earlier by Jamin), the beams are reunited at F by the lens L_2. Fringes appear at the lens focus and are viewed with a high-magnification cylindrical lens.

As shown in fig. 1(B), T_1T_2 occupy only the upper half of the field of view so that similar systems of fringes appear at F_1 and F_2, the lower set at F_2 becoming a reference-fixed system, which is brought close to the movable system at F_1 with the tilted glass plate H. The Jamin compensator G_1G_2 consists of two similar glass plates inclined at a small angle, the beam from the two separate slits going through separate plates. By a slight rotation, a

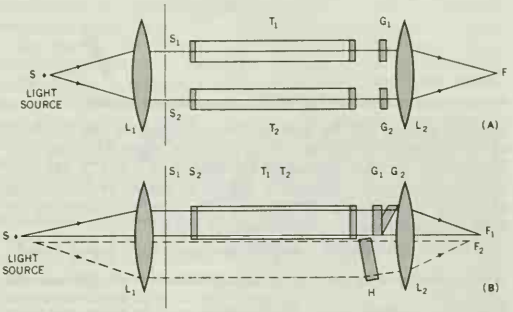

FIG. 1.—(A) PLAN AND (B) ELEVATION DIAGRAMS OF THE INTERFERENCE REFRACTOMETER

small path difference can be introduced into either path so as to compensate any differences created in T_1 and T_2 by differential gas filling. The fringe displacement per degree of rotation is predetermined with light of known wave length, the final observations being made with white-light fringes; for by this means the central achromatic white-light fringe enables exact identity of path to be re-established with the compensator. If one tube is evacuated, then for a tube length L the refractive index μ is given by $n\lambda = (\mu - 1)L$ in which λ is the wave length of the calibrating light and n the number of fringes which the compensator reintroduces. A shift of $\frac{1}{10}$ fringe is just measurable, and for tubes 1 m. long this corresponds to a change in refractive index of 1×10^{-8}.

1. The Väisälä Interferometer.—A striking adaptation of this interference system was introduced by V. Väisälä (1927) for the purpose of measuring very long paths (*e.g.*, of the order of 100 m.) for use as a base line in geodetic survey. Two arrangements were used. In the first (fig. 2), light from S, separated by the two slits S_1S_2, produces fringes at F, after reflection from mirrors A, B, C. If white light is used, then fringes are only seen if AB is equal to BC to within a light wave or two. If AB is a substandard metre then BC can be matched equal to this to within a fraction of a light wave. The length AC is now 2 m. BC can now be

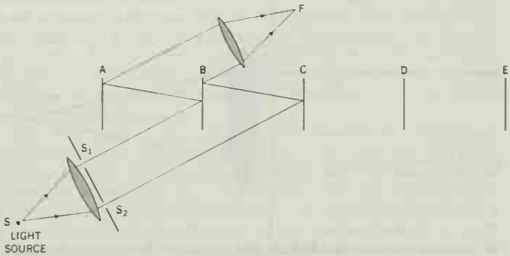

FIG. 2.—INTERFERENCE SYSTEM INTRODUCED BY V. VÄISÄLÄ

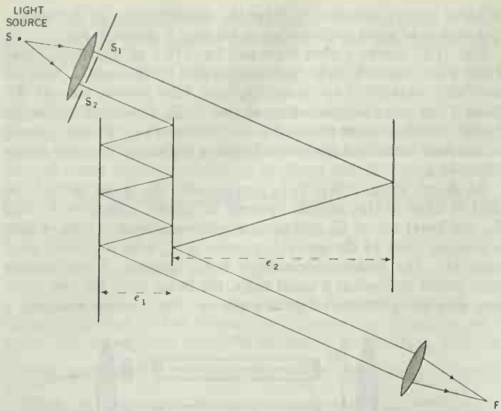

FIG. 3.—MODIFICATION OF THE VÄISÄLÄ INTERFERENCE SYSTEM

matched against CD by altering the inclination of the incidence of the beams on the mirrors, so an accurate length AE is secured. The system does not depend on the lengths of AB, CD, etc., but on their differences. Because of difficulties caused by inclinations of beams, atmospheric disturbances and earth microtremors the method is restricted to an upper limit of 100 m.

In a later modification a step-up procedure was adopted as indicated in fig. 3. In practice a step-up ratio $\frac{e_2}{e_1}$ of 5:1 was the largest that could be used. To determine 50 m. to within one wave length is a precision of one part in 10^8.

2. Michelson's Stellar Interferometer.—In 1868 Fizeau described an elegant method for measuring the angular separation between two distant objects (slits or stars) by superposing and confusing the independent fringe patterns given from each source by a two-slit device which divided the separate wave fronts from each source. Thus, in fig. 4, let F be the fringe pattern from the one source appearing at the lens focus. Let the other source produce a similar pattern at F_1. If the F_1 fringe system is displaced from the F fringe system by half a fringe width, then maxima fall on minima, and no fringes are visible. This happens when the angular separation of the two slit sources (θ) equals $\frac{\lambda}{2a}$, or odd multiples thereof. By this technique, J. M. Stephan (1878) tried to measure the angular diameters of stars. He failed insofar as stellar distances are so great that no available telescope had an aperture big enough to give an a value sufficiently large. The first success on astronomical objects was achieved by A. A. Michelson in 1890, who with the large Lick telescope determined the angular diameters of Jupiter's moons (some 1 sec. of arc). Then in 1920 Michelson hit upon the ingenious device of effectively increasing a by building large girder extensions onto a massive telescope, thus constructing his celebrated stellar interferometer. The method as applied to a refracting telescope is shown in fig. 5. B and C are small rectangular mirrors fixed over the telescope objective, E being a screen to cut out direct light from the star. The mirrors A and D can be moved out symmetrically. In effect the aperture of the system (a) becomes AD. Now while for two separate point sources the fringe dissonance occurs at $\theta = \frac{\lambda}{2a}$ it can be shown that a dissonance will also be produced by the separate parts from one disk-shaped source of angular diameter θ, and this occurs when $\theta = \frac{1.22\lambda}{a}$.

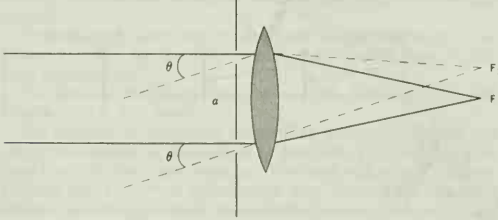

FIG. 4.—METHOD FOR MEASURING THE ANGULAR SEPARATION BETWEEN TWO DISTANT OBJECTS, DESCRIBED BY A. H. FIZEAU IN 1868

For the first star examined, Betelgeuse, the fringes vanished when a was 10 ft. 1 in., leading to an angular diameter θ of a mere 0.05 sec. of arc, a quantity far too small to be detected even by the largest telescope using ordinary visual methods. An extensive program was under way in the early 1960s in several observatories, and many stellar diameters have been determined.

II. INTERFEROMETERS USING DIVISION OF AMPLITUDE

The first interference effects seriously studied, Newton's rings, involved division of amplitude. A fraction of the amplitude of an incident plane wave front is reflected from one face of a thin film and a second comparable fraction from the other face, the two recombining to give interference fringes. If very strict attention is paid to parallelism of the incident light, the two faces need not be close together and can indeed be centimetres apart. The fringes produced by division of amplitude are governed by the expression $n\lambda = 2\mu t \cos\theta$ in which n is the order of interference, t the separation between the two surfaces in medium of refractive

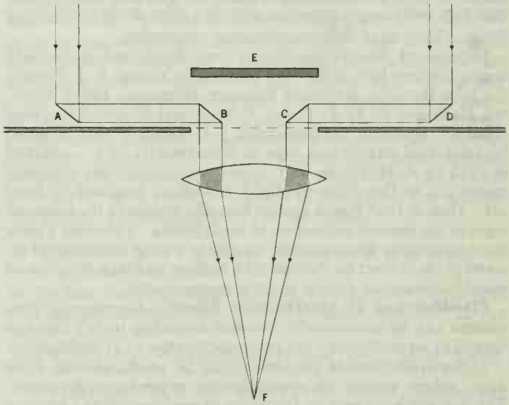

FIG. 5.—DIAGRAM OF STELLAR INTERFEROMETER DEVELOPED BY A. A. MICHELSON IN 1920

index μ and θ the angle of incidence. It is often convenient to use an air medium (taking μ as unity) and parallel light of normal incidence ($\cos\theta = 1$); then with light of one wave length the fringes follow any variations in t. They are therefore called fringes of equal thickness. If, on the contrary, t is constant (*i.e.*, parallel-sided plates), then by using an extended range of angles of incidence (a range of θ values) there result circular ring fringes. First discovered by Haidinger in 1849, these are called fringes of equal inclination since each arises as the envelope or locus of rays making the same inclination to the normal to the plates.

Interferometers which use fringes of equal thickness will be considered first. Fizeau's classical determinations (1861–64) of the thermal expansions of small polished crystals, using a variation of Newton's rings, introduced the first interferometer explicitly using division of amplitude for metrical determinations. A modern variant (U.S. bureau of standards) is shown in fig. 6.

A, the main surface of which is optically plane, is cut from fused quartz, which has a low thermal expansion. On a polished knife-edge at B rests a quartz optical flat. The specimen C whose expansion is required is cut so that there remains a thin air film

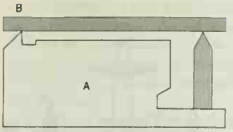

FIG. 6.—MODERN VARIANT OF AN INTERFEROMETER USING DIVISION OF AMPLITUDE

between A and B, with the two surfaces nearly parallel. Between these, the localized wedge fringes of equal thickness are formed with monochromatic collimated light. On heating C, the relative expansion of C to A leads to movement of the fringes. A correction for the small expansion of A is predetermined by using as C a material of known expansion.

1. Fizeau-Laurent Surface Interferometer.—An optical system, originally described by Fizeau (1862), was adapted by L. L. Laurent (1883) into an interferometer now extensively used in the optical industry. It reveals departures of polished surfaces from the plane, and enables the optical polisher to see and remove surface defects. The system is shown in fig. 7. A small pinhole A, at the focus of a well-corrected lens L, is illuminated with monochromatic light. The surfaces to be matched are a reference plane C_1 and the workpiece C_2. Incidence on C_1 is normal; and by setting a slight angle between the two surfaces, fringes of equal thickness are seen at E through interposition of a reflector at D. Laurent was the first to realize that these fringes constitute a contour map of the surface, being in effect contour lines which change successively in height by $\frac{\lambda}{2}$. It is this fact which proved so valuable to the optical industry. An interesting extension was proposed in 1893 by Lord Rayleigh, who pointed out that a steady liquid surface could be used as a reference plane. The workpiece can be held either above or below the surface. H. Barrell and R. S. Marriner (1940) tested the flatness of quite large plates in this way and had no difficulty in detecting errors as small as $\frac{\lambda}{10}$. Curvature of the earth causes a hillock $\frac{\lambda}{500}$ high over a 25-cm. diameter disk, and it is found that surface tension effects vanish 2.5 cm. from the disk boundary.

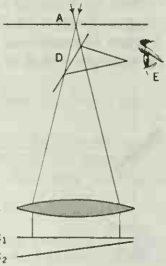

FIG. 7.—FIZEAU-LAURENT SURFACE INTERFEROMETRY SYSTEM

2. The Jamin Interferometer.—In 1856 Jamin described an interference refractometer which exploited the fringes of equal inclination discovered by Brewster in 1817. Brewster fringes form when light is reflected back from two identical thick parallel plates inclined at a slight angle to each other. Jamin used Brewster fringes formed under the special condition of 45° incidence as illustrated in fig. 8. Two thick identical glass blocks, P and Q, are set nearly parallel. The shaded faces are heavily silvered. A narrow beam of parallel light, incident at A, divides and traces the two paths ABCD and AFGD, recombining as two beams of the same intensity in the direction E, where straight line fringes of equal inclination are observed with a telescope set on infinity. Secondary reflections such as GP and DH are cut out by suitable stops. The two plates I and J constitute the Jamin compensator. Initially the two tubes T_1 and T_2 are evacuated, and with white light the central achromatic white fringe is set on the telescope cross wire. Introduction of gas into one tube leads to a fringe displacement; and the fringes are then brought back with the compensator, which has been precalibrated with monochromatic light.

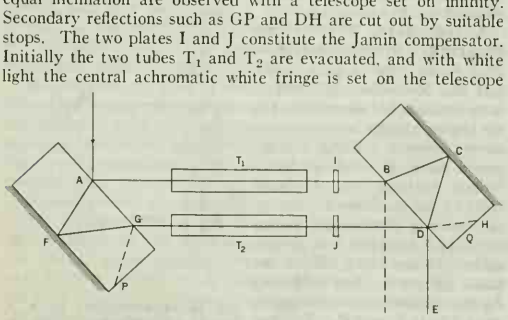

FIG. 8.—INTERFERENCE REFRACTOMETER DESCRIBED BY J. C. JAMIN IN 1856

3. The Michelson Interferometer.—It is probable that no single instrument has more profoundly influenced modern physics than the Michelson interferometer (1881). With it Michelson laid the experimental foundation to the theory of relativity, established the existence of hyperfine structure in line spectra, standardized the metre in terms of light waves and measured the tidal effect of the moon on the earth. Modifications have been used for testing lenses and prisms, as refractometers and also for the examination of surface microtopographies.

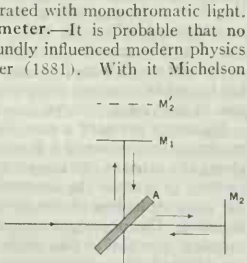

FIG. 9.—A. A. MICHELSON INTERFEROMETER (1881)

The instrument consists of a half-silvered mirror A (fig. 9) which divides a light beam incident at 45° into two equal parts, one of which is transmitted to the mirror M_2 and the other reflected to the mirror M_1. The beams retrace their paths and recombine in the direction B where fringes form. An observer looking along BA sees the mirror M_1 and also M_2', the image of M_2. The mirror M_2 can be moved parallel to itself with a fine-pitch screw on an accurately machined bed. Both M_1 and M_2 can be tilted with screws. The observer sees fringes formed in the air film M_1M_2'. If the two planes M_1 and the virtual image M_2' are parallel, then circular fringes of equal inclination appear. If they are inclined, then fringes resembling wedge fringes are seen. If, further, the two planes intersect, then where they cross, white-light fringes are obtained (*i.e.*, in the region near to zero path difference). A means is thus available for setting AM_2 equal to AM_1 to within a small fraction of a light wave, usually estimated to be about $\frac{\lambda}{80}$.

To secure these white-light fringes, the two optical paths AM_1 and AM_2 must be the same for all wave lengths. Since the reflecting film A is on the front of a glass block, an identical compensating block is placed parallel to A in the path AM_1.

One of the first applications of this instrument was the carrying out of the celebrated Michelson-Morley experiment (*see* RELATIVITY; MICHELSON-MORLEY EXPERIMENT), an attempt to measure the relative motion between earth and ether. The interferometer was set up with equal arms, and rotated so that at one time light traversed AM_1 along the direction of motion of the earth and shortly after this in a contrary direction. With the particular instrumental dimensions used, computation predicted a fringe shift of 0.4 of a fringe. No shift exceeding 0.04 of a fringe was found. On this null result the whole superstructure of relativity physics was constructed.

R. J. Kennedy confirmed the result in 1926, using a greatly increased sensitivity. On the mirror A and across half of it he deposited an extra silver film of thickness $\frac{\lambda}{20}$. At the boundary the fringes showed a discontinuity of $\frac{1}{10}$ of a fringe. Broad fringes were arranged to give a practically uniform tint of the illumination on either side of the step, both sides being equally off the true maximum. A very small displacement led to one side, brightening up relative to the other. Indeed, the remarkably small quantity of $\frac{1}{1,000}$ of a fringe was detectable, corresponding to an optical path change of a mere 2.5 Å.

The Structures of Spectral Lines.—Of considerable importance to atomic nuclear physics is the study of nuclear spin and magnetic properties obtained from measurements of the hyperfine structures of spectral lines. Such structures were first detected by Michelson using his interferometer. In 1891 Michelson made a systematic study of the visibility of the fringes given by a range of spectroscopic lines. Defining fringe visibility from the intensity of the maxima and minima as $(I_{max} - I_{min})/(I_{max} + I_{min})$ he

plotted these visibilities as a function of the separation between the interferometer plates. The visibility is determined only by the width and complexity of the spectral line. For a theoretically monochromatic line the visibility curve is a horizontal straight line, but of course even a single line has a width due to a variety of factors, which leads to a smooth curve. If in addition the line has hyperfine structure components, then maxima and minima appear in the visibility curve.

Michelson invented a most ingenious harmonic analyzer which mechanically performed a Fourier analysis on the visibility curve, giving the original line shapes and line structures which had synthesized to produce the observed visibility curve. By this means the close structures of the lines of the hydrogen spectrum were obtained. One important observation was the finding that the red cadmium line 6438 Å was single and narrow. Thereupon Michelson adopted this narrow line as his standard in his next classical research, namely the evaluation of the standard metre interferometrically in terms of light waves.

Evaluation of the Metre With Light Waves.—The metre is internationally defined as the distance between two fine scratches on a bar of platino-iridium kept at Sèvres, near Paris. Michelson (1892) set himself the problem of counting the number of red cadmium light waves in this length. The line width is such that no fringes are visible with a path difference exceeding 20 cm., and in any case there are about 1,500,000 waves to the metre. Thus a system of subdivided standards, called etalons, was adopted. The first was 10 cm., and this was halved progressively eight times to 0.3906 mm., a length containing about 1,200 fringes and therefore reasonable for direct counting. The number of fringes in this smallest etalon A was directly counted by matching its front face against the interferometer movable mirror, retracting the latter slowly and counting until the mirror coincided with the back face. Coincidence was assured with white-light fringes, but the counting was carried out in red cadmium light. This etalon was doubled up against the next etalon B, and the only measurement which then had to be made was the difference $B \sim 2A$. This procedure was repeated until the exact length of the 10-cm. etalon was obtained. Finally this was stepped up ten times against itself, and this exactly known length then matched against the standard metre. The final result, given to 1 part in 2,000,000, was 1,553,163.5 red cadmium waves to the metre.

4. The Twyman-Green Interferometer.—In 1916 F. Twyman and A. Green introduced a slight modification, adapting the Michelson interferometer for lens and prism testing, and this became standard equipment in optical workshops. The essential feature is the introduction of strict Fizeau-type collimation by using a point source of monochromatic light at the focus of a well-corrected lens. The way in which the interferometer is used for testing a prism is shown in fig. 10 and for testing a lens in fig. 11. With a perfect prism P, a plane wave incident on P returns as such to D and a uniform field of illumination is seen. Local errors, either of surfacing or as knots in the glass with different refractive index, distort the wave front. The optician can then suitably correct these by working the glass until the emerging wave front is plane.

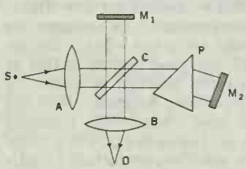

FIG. 10.—TWYMAN-GREEN INTERFEROMETER (1916) AS IT IS USED FOR TESTING A PRISM

For testing the lens L the plane mirror M_2 is replaced by a convex mirror M and the light strikes this normally, to retrace its path. Imperfections in the lens result in fringe distortions which can be interpreted in terms of spherical aberration, coma, astigmatism, etc.

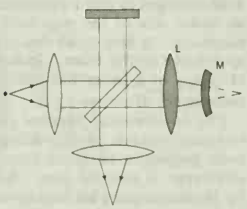

FIG. 11.—TWYMAN-GREEN INTERFEROMETER AS IT IS USED FOR TESTING A LENS

5. The Linnik Interference Microscope.—A valuable modification was the interference microscope of W. Linnik (1926), which permits evaluation of surface microtopography to fringe accuracy in the up-down direction, and with magnifications up to 1,000 times across the surface in extension. The system is shown in fig. 12. A is the beam splitter, P the surface under examination and Q a reference flat. L_1 and L_2 are carefully matched high-power microscope objectives (usually 4-mm. lenses) so that L_1 together with lens systems L_3 L_4 constitutes a high-power microscope. One sees through this the surface P crossed with the fringes formed by P and Q so that the microtopography is contoured by fringes. Several interference microscopes were developed in which division of amplitude takes place in a specially designed objective. An example is that of J. Dyson (1950).

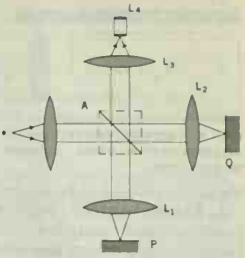

FIG. 12.—SYSTEM OF LINNIK'S INTERFERENCE MICROSCOPE (1926)

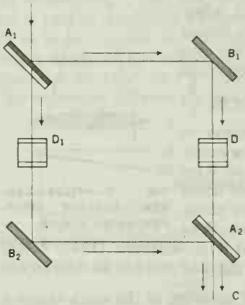

FIG. 13.—MACH-ZEHNDER INTERFEROMETRY SYSTEM, DEVELOPED IN 1891

6. The Mach-Zehnder Interferometer.—Ernst Mach and L. A. Zehnder (1891) independently developed a modification of Jamin's interferometer, which though difficult to adjust has been widely used for studying air flow around models of aircraft. The system is shown in fig. 13. The mirrors A_1 and A_2 are half-silvered while B_1 and B_2 are fully silvered on the front faces. The object (aerodynamic model) is supported in the air chamber D through which a high-velocity air jet is blown. D_1 is an identical compensating chamber. Local pressure variations, due to flow, lead to local refractive index changes so that the flow pattern is revealed by fringe distortions.

There are two reasons why this instrument is better than Michelson's for aerodynamics. First, the optical circuit is such that the light traverses the observation chamber one way only, whereas in Michelson's instrument it passes and returns. Strong local refractive index variations have a prismatic action and displace the beam which would not quite retrace the same path on the return journey. Second, and more important, is the question of fringe localization. In Michelson's instrument the fringes are localized on the mirror M_1 (*see* earlier figures) whereas in the Mach-Zehnder system the fringes can be placed so as to coincide with the object in D. Thus both object and fringes can be photographed sharply in focus.

7. The Bates Wave-Front Shearing Interferometer.—W. J. Bates (1947) slightly modified the Mach-Zehnder system, with considerable advantages for the testing of large lenses or large curved mirrors. Using a collimated beam, he produced interference between two displaced parts of the same wave front by the shearing arrangement shown in fig. 14. A perfect lens gives a spherical wave which falls on the beam splitter A_1, and by tilting A_2 one secures two overlapping wave fronts Y and Z. The images from these wave fronts can

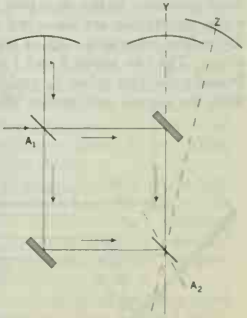

FIG. 14.—ARRANGEMENT OF W. J. BATES'S WAVE-FRONT SHEARING INTERFEROMETER (1947)

be localized on A_2 and if these wave fronts are truly spherical, then any tilting of A_2 leads to no change in the field of view. If the wave front departs from the spherical, changes are seen which can be interpreted. Important is the fact that a large mirror or lens is matched against itself so that a large reference plane is not required.

8. The Fabry-Pérot Interferometer.—Ranking almost in importance optically with the Michelson interferometer is that of C. Fabry and A. Pérot, which has an interesting history. In 1836 G. B. Airy had computed the effect on interference fringes of taking into account the successive multiple reflections (neglected previously because of negligible intensities). He showed that if light is incident at angle θ onto a plane parallel plate of thickness t then the transmitted intensity has the form

$$\frac{1}{1+\frac{4R}{(1-R)^2}\sin^2\left(\frac{2\pi\mu t}{\lambda}\cos\theta\right)}$$

in which R is the reflection coefficient. This formula remained a forgotten academic curiosity until A. Boulouch in 1893 drew attention to the fact that when the reflectivity R is high (say, exceeding 80%) then this formula establishes that a profound sharpening in the fringes will take place. Indeed, Boulouch showed this to be the case experimentally.

However, it remained for Fabry and Pérot (1897) to realize the full implication of this when they produced their celebrated variable-gap interferometer. This consists of two very accurately worked planes (errors not exceeding $\frac{\lambda}{80}$ in the best instruments) maintained by optically worked spacers strictly parallel, to within a quite small fraction of a light wave. The two plates, called an etalon, are coated with a thin transmitting film of high reflectivity (originally sputtered silver). Reflectivity should exceed 90%, and with modern techniques 95% and even 97% reflectivities are achieved with only perhaps 1.5% absorption, the rest being transmitted. Special techniques are needed to secure such low absorptions.

This simple instrument is an extremely powerful optical system. Being essentially a parallel air plate, it produces Haidinger rings, localized at infinity. However, the important feature is that the successive multiple reflections, diminishing very slowly in intensity because of the high reflectivity, lead to the formation of very sharp narrow fringes. Fringes can be defined by their half width; *i.e.*, that fraction of an order occupied by the width at a region where the fringe intensity is half the peak maximum value. For 95% reflectivity the half width is about $\frac{1}{60}$ of an order separation, and as one can set to $\frac{1}{5}$ of a fringe width, this setting corresponds to $\frac{1}{600}$ of a wave length. Only a brief résumé can be given of the many and varied uses of this interferometer.

Analysis of Hyperfine Structures in Line Spectra.—The instrument is very widely used for the high resolution needed for revealing hyperfine structures in line spectra. At a wave length of 5000 Å, a reflectivity of 95% and a plate separation of 10 cm. (which has been used) give a resolving power of 20,000,000, so that one can resolve components separated by a mere 0.00025 Å. Compare this with the resolving power of 100,000 available in the first order of a typical high-quality large diffraction grating.

Measurement of Line Width.—The high resolution and high dispersion enable the instrument to be used for evaluation of the widths of even quite narrow spectral lines. For example, interesting conclusions have been drawn about the temperatures in the upper atmosphere from measured line widths of auroral spectral lines.

Determination of Precision Wave Lengths.—The Fabry-Pérot interferometer is the standard instrument for accurate determination of the wave lengths of spectroscopic lines. By the use of three standard wave lengths (the cadmium lines 6438.4916 Å, 5085.8220 Å and 4799.9088 Å), each of which has been directly interferometrically evaluated against the standard metre, the spacing of the interferometer plates can be derived with high accuracy. Then, from the measurement of the diameters of the fringes of the spectral lines under study, their wave lengths can be computed from the knowledge of this spacing, with an accuracy, in the best cases, of ± 0.001 Å.

The Evaluation of the Metre.—J. R. Benôit, Fabry and Pérot (1913), combining the principles of the Brewster fringes with that of the Fabry-Pérot interferometer, redetermined the metre.

Multiple-beam Brewster fringes are produced in transmitted light by two Fabry-Pérot interferometers in series behind each other, their lengths being in the ratio 2:1. First the exact spacing in terms of the red cadmium line is found interferometrically for an interferometer with as near as possible a 6.25-cm. spacing. This is then matched, by Brewster fringes, against a 12.5-cm. etalon, then this against a 25-cm., then this against a 50-cm. and finally the last is matched against an approximate 1-m. etalon. This etalon, the length of which is exactly known in wave lengths, can be compared with the standard metre quite rapidly, since only the difference is required.

Between Michelson's 1892 experiment and 1940, nine precision determinations were made by different laboratories; and the mean wave length for red cadmium was found to be 6438.4696 ± 0.0010 Å, which by chance was exactly the value adopted by international agreement in 1907.

Refractive Index of Air.—The etalon gives the best values for the refractive indices and dispersions of gases. The exact metrical spacing of an enclosed interferometer is first found *in vacuo*. Then the new optical path is measured when air (or gas) is introduced. As typical of modern precision the refractive index for air (at 760 mm., temperature 15° C. and 0.03% CO_2 content) for the red cadmium line is given by H. Barrell and J. E. Sears (1939) as 1.000276380.

9. The Echelon and Lummer Plate Interferometers.—The echelon interferometer of Michelson and the Lummer plate interferometer, both used in spectroscopy, are discussed elsewhere (*see* SPECTROSCOPY) and need only be mentioned here.

III. MULTIPLE-BEAM INTERFEROMETRY

What is called multiple-beam interferometry is an important extension made by S. Tolansky (1946) of Boulouch's multiple-beam principle to include the case of wedge interference systems. The Fabry-Pérot interferometer was concerned with the circular fringes given by thick parallel plates. Such fringes arise from integration of light across the interferometer plates, hence the necessity for extreme flatness and parallelism. Tolansky showed how the multiple-beam principle could be applied to thin-film localized wedge fringes; and succeeded in securing for topographical studies that same increase in power and sensitivity which the Fabry-Pérot interferometer had given to metrological and spectroscopic studies. With highly reflecting plane surfaces inclined at a small angle, multiple reflections can lead to highly sharpened wedge fringes as shown in fig. 15.

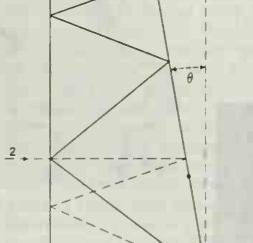

FIG. 15.—MULTIPLE-BEAM INTERFEROMETRY AS DEVELOPED BY S. TOLANSKY IN 1946

Three successive beams, 1, 2, 3, are shown meeting at the point D. The beams are not in arithmetical phase behind each other, for the nth beam lags behind the arithmetical progression by an amount $X = \frac{4n^3\theta^2 t}{3}$ in which AD = t. Only if X is appreciably less than $\frac{\lambda}{2}$ will the necessary condition for Airy summation hold, to produce very sharp fringes. Since effective values of n up to some 80 are involved, sharpening takes place only if t is very small, indeed of the order of one or two light wave lengths.

FIG. 16.—SOME APPLICATIONS OF MULTIPLE-BEAM INTERFEROMETRY (*see* TEXT)

In the Fabry-Pérot-type fringes the fringe shape is determined by the term $\frac{4R}{(1-R)^2}\sin^2\left(\frac{2\pi\mu t}{\lambda}\cos\theta\right)$ in which the only variable is θ. In multiple-beam localized wedge fringes the same formula holds, but θ is constant and the variable is t. The fringe widths in the two systems obey a similar relation.

The surfaces to be studied are coated with a high reflector, placed very close together and illuminated from a small pinhole with strictly collimated monochromatic light at normal incidence. The resulting considerable improvement in fringe sharpness is shown in fig. 16. In (E) are shown Newton's rings obtained with two beams and in (F) the same secured with multiple beams. In the other sections, a selection is given from some of the studies made by Tolansky employing multiple-beam methods.

Some Applications of Multiple-Beam Interferometry.—*Microtopographies of Surfaces.*—A new high order of accuracy has been achieved in the study of surface microtopography. The fringes are contour lines of 2500 Å height. Fringes are of the order of some $\frac{1}{50}$ wide, and displacements of $\frac{1}{4}$ of a fringe width are clearly measurable. Thus step heights of 10 Å can be recorded, a quantity of molecular dimensions. Indeed crystal lattice spacings of from 12 to 20 Å have been measured to within 1 Å.

Fig. 16(H) shows the fringe pattern at a cleavage step on mica; such pictures establish that the steps are small integral multiples of the lattice spacing. Many crystals reveal beautiful topographies; fig. 16(I) shows a complex microtopography on the octahedral face of a diamond (*see* CRYSTALLOGRAPHY).

Experimentation has established that vacuum deposition of silver by thermal evaporation leads to strict contouring by the silver of the surface features, even down to molecular dimensions.

Thickness of Thin Films.—The multiple-beam interferometer is widely used for the precise measurement of the thicknesses of thin films. The film is coated with an opaque layer of silver, extending over the film boundary so that a step appears in this thick silver film equal in height to the original film being measured. This step is then measured against a silvered optical flat with multiple-beam fringes in reflection. Film thicknesses as small as only 25 Å can be measured. Fig. 16(B) shows the fringe pattern given by a film 550 Å in thickness. The fringes are very narrow and the accuracy in the step measurement is high.

Oscillations of Piezoelectric Crystal Plates.—Quartz plate oscillators play an important part in precision electronic circuitry as frequency stabilizers and precision clocks. A most interesting application reveals the distribution of nodes and antinodes and the exact local values of amplitudes on such oscillators. The crystal surface, polished and silvered for interferometry, is one electrode, and a wire meshwork is the other. The silvered crystal rests on a silvered optical flat. When set into oscillation the initially straight line fringes take on a stationary pattern which reveals the distribution of the vibration, and the local fringe shape gives an exact measure of the amplitude. Fig. 16(A) shows a vibrating bar and fig. 16(D) a vibrating disk. Frequencies in both cases are several kilocycles, yet the patterns are completely stationary.

Fringes of Equal Chromatic Order.—Tolansky in 1946 developed a system of white-light multiple-beam fringes which have considerable power and are advantageous in specific instances. Their formation is shown in fig. 17. A white-light source A is imaged on a small aperture C and a parallel beam directed at normal incidence onto the silvered pair of interferometer surfaces E. The two surfaces must be very close together, but it is advantageous if they are near parallelism rather than wedged. With the achromatic lens F an image of E is projected onto G, the slit of a spectrograph, which thus selects a very narrow section of the surface under examination. Sharp multiple-beam white-light fringes form at H, each fringe being the locus of points for which $\frac{t}{\lambda}$ is constant. They have been named fringes of equal chromatic order.

FIG. 17.—FORMATION OF WHITE-LIGHT MULTIPLE-BEAM FRINGES

For discontinuous steps, these fringes offer advantages. Examples are shown in fig. 16(C) which illustrates the fringes of equal chromatic order given by a silvered Newton's rings lens-plate combination. Fig. 16(J) illustrates the fringe pattern given by a very small surface depression with a depth of 4×10^{-6} cm. Each fringe is a contour line-profile over the same region on the object, but of different wave length. The separation between fringe pairs can be made very great. Magnifications of 500,000 times, with resolution of 10 Å, can readily be obtained. These great powers are in the up-down direction only.

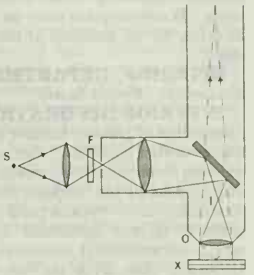

FIG. 18.—ARRANGEMENT WHEN A METALLURGICAL TYPE OF MICROSCOPE IS USED TO STUDY OPAQUE OBJECTS

Studies on Opaque Objects (Metals, etc.).—Many problems connected with surface flow, hardness indentation testing, crystal dislocation movements, electrodeposition, etc., on metal surfaces have been studied with the multiple-beam interferometer. A metallurgical type of microscope must be employed with the arrangement shown in fig. 18. From a source S a point image I is formed at the back focal plane of the microscope objective O. The objective must illuminate the interferometer system with strictly parallel light at normal incidence and at the same time give a good microscopic image of the object X. As an example, fig. 16(G) shows the distortions produced on a metal surface which has received a small micro-indent from a diamond pyramid, a procedure used in testing metal hardness. The distorted pattern is of crystallographic interest; for this indentation has been made on the surface of a single crystal of tin. The interference pattern indicates the character of the surface-flow distortion which results from the indentation. The asymmetry is even more marked than at first appears; for the extended horizontal lobes are elevations, while the smaller lobes at right angles to these are depressions. This shows that in one direction the surface "piles up," while at right angles to this it "sinks in." In fact, X-ray examination shows that these lobes lie along crystallographic axis directions. They reveal a differential directional hardness variation in the tin crystal. Such interferometric studies have already revealed much new information about surface-flow phenomena when materials are distorted. (*See* X-RAYS: *Modern Industrial Applications.*)

In the 1960s, with the extension of maser devices into the range of visible light (lasers) and the infrared spectrum (irasers), interferometry was in the process of making further strides forward. These first generally available optical masers incorporated interferometers in their construction and provided substantial improvements over ordinary sources of light in terms of such characteristics as intensity, coherence and monochromaticity (*see* LASER; MASER). *See* also references under "Interferometer" in the Index.

BIBLIOGRAPHY.—The long article on interferometry by W. Feussner and L. Janicki in E. Gehrcke's *Handbuch der Physikalischen Optik*, 2 vol. (1927), is detailed and learned. *See* also C. Fabry, *Les Applications des interférences lumineuses* (1923); A. A. Michelson, *Studies in Optics* (1927); A. C. Candler, *Interferometers* (1951); S. INTER-GOVERNMENTAL MARITIME CONSULTATIVE ORGANIZATION (IMCO), a specialized agency of the United Nations, came into existence on March 17, 1958, and was organized in Jan. 1959. IMCO was established to promote international co-operation in maritime navigation and encourage the maximum use of safety measures; to encourage also the removal of discriminatory action and unnecessary restrictions by governments affecting international shipping; and to consider matters concerning unfair restrictive practices by shipping concerns. It concentrated early on technical aspects of shipping such as safety at sea, pollution of the sea and tonnage measurement of ships.

INTERIOR, DEPARTMENT OF: *see* GOVERNMENT DEPARTMENTS: *United States*.

INTERIOR DECORATION. This article is devoted to the preparation of plans of interior decoration for both residential and nonresidential buildings. The major part of the article is devoted to living accommodations, where the major portion of the planning may be done by the resident; included are detailed suggestions for treatments of the various parts of the interior. The general principles of interior decoration discussed in this section apply as well to nonresidential structures, where the interior decoration is frequently done by a professional interior designer. The final section of this article gives a brief account of the development of the interior design profession and of the procedures followed by a professional designer in planning a commercial interior.

For period decoration *see* INTERIOR DECORATION, HISTORY OF. Other articles of related interest include HOUSING, a broad general discussion; HOUSE DESIGN, on the planning and building of a single-family dwelling; RESIDENTIAL ARCHITECTURE, a historical account of buildings for human habitation; LANDSCAPE ARCHITECTURE; and MODERN ARCHITECTURE. Articles on the various elements of interior decoration, such as rugs and carpets, are referred to at appropriate places in the text of this article, which is divided into the following main sections:

I. RESIDENTIAL INTERIORS

A. BASIC CONSIDERATIONS

1. Planning Aims.—The approach to any scheme of interior design or decoration should be analytical so that the precise nature of the problem is understood. The aim of redecorating or replanning a building, or part of a building, is obviously both to improve its appearance and to make it more convenient. The drawbacks to the existing structure must be perceived clearly; for instance: Does it cause irritation and fatigue? Have space requirements changed so that certain areas are not used adequately? What are to be the most important functions of the new surroundings? All possible improvements should be considered and defined in order of priority; even if the cost makes it impossible to carry out the complete scheme at once, there should still be an over-all plan since improvements that have been treated piecemeal invariably give less satisfactory results. One of the commonest mistakes is lack of this foresight.

Unity of effect is most important in providing a satisfying interior. While the taste and character of the occupants should be expressed, a measure of restraint and adherence to an over-all plan gives better results than selecting colours, patterns or pieces of furniture in isolation. These may be well designed in themselves but unsuitable when related to the whole. It is in visualizing these relationships between the component parts that the principal difficulty lies, and reference to well-illustrated books and periodicals often helps the amateur to compare different amalgamations of colour and design.

Completely matching suites of furniture can give an impression of monotony but the confusion caused by too many different shapes and designs is equally to be avoided; pleasing decoration is often achieved by a balance between the two. Furnishings of many periods may combine satisfactorily provided there are similarities in their style; for instance, modern Scandinavian textiles and furniture, with their emphasis on texture of weave or grain of wood, may blend happily with early American Colonial wood furniture, and some sophisticated new Italian pieces can fit in with elegant Regency furniture.

Most modern dwellings are comparatively small, and, as they still must provide for the varied needs of a family, flexibility is usually desirable. This may be achieved by replacing fixed walls and furniture with sliding wall panels, folding doors, roll-down partitions, portable screens or storage units.

(E. C. D.; G. A. E.)

2. Space Organization.—Evaluation of individual and family activities is the starting point in organization of space in an interior. At this stage it is most helpful to think in terms of functions rather than fixed spaces. For example, the function of eating may be fulfilled in places other than a dining room. Likewise, it is helpful to consider "food preparation" rather than "kitchens"; "quiet recreation," "noisy recreation" and "entertainment of guests" rather than "living rooms"; "storage of specific items" rather than "closets"; etc. Flexible arrangement of space is usually highly desirable because of the modern tendency toward construction of relatively small living units despite varied family demands. The Japanese home with its movable wall panels and minimal furnishings achieved flexibility more successfully, perhaps, than any other. Relatively large areas of space unobstructed by fixed walls or furnishings may be used in a variety of ways, simply by rearrangement of furniture or movable partitions.

Often in the remodeling of old homes the first step is to remove some of the fixed walls and partitions in order to achieve greater flexibility and openness. Another way of achieving openness in an area without loss of privacy is to extend a partition wall only part way to the ceiling; in fact, a wall may be open at the bottom as well as at the top. The same effect of openness may be achieved by a storage wall that does not extend to the ceiling. Sometimes the fireplace may be located so that it serves as a partial divider between living and dining or food preparation areas, yet neither area is closed-in or isolated.

Window walls or large picture windows also bestow an illusion of greater space but are scarcely satisfactory unless there is a fine view outside and provision is made for privacy and lack of glare inside. Also, some transition between inside and outside is often thought desirable, for instance, a miniature garden border indoors, or a terrace, porch or balcony. A sense of unlimited space, however, is to be avoided, as it tends to make the inhabitants feel vulnerable. An impression of security is often created by lowering a section of the ceiling.

In a number of homes designed by Frank Lloyd Wright, for example, a low ceiling over the fireplace contrasts with an adjoining area where a long view of a garden or landscape may be emphasized by a high ceiling. The same effect has been achieved in some old, large, high-ceilinged interiors through remodeling. A comfortable sense of seclusion can be achieved also, by dividing large areas into smaller ones with screens, wall panels or storage units, or furniture groupings, or by using warm colours, such as yellows,

oranges, reds and warm beiges and browns.

An illusion of spaciousness, on the other hand, is created by arranging the furniture near the edges of the room and furnishing in cool and relatively light colours, such as medium to light blues, greens, cool grays and off-whites. The illusion of space is also strengthened by mirrors and by paintings employing perspective, especially if placed where they can be seen from some distance.

The specific areas to be planned for in homes include the following:

General Living Areas.—Some means of dividing the area is desirable in order that various incompatible activities can be pursued simultaneously. Many people find that a satisfactory solution is to have two rooms, a small one for reading or conversation and a larger one for more active hobbies and children's games. Provision also must be made for television viewing, the set being best placed in the fireplace wall, or in a storage wall where it can be enclosed when not in use.

Dining Space.—A great number of houses are designed with the dining area at one end of the living room or in an adjoining area, an arrangement which has the advantage of flexibility. Some people prefer to eat in a large kitchen-dining room, others more formally in a separate room. In each case, however, it is essential that the cooking arrangements should be easily accessible. Comfortable furniture, adequate cupboard space, pleasant lighting, a good view and an adjoining outdoor dining space are added advantages.

The Kitchen Area.—Kitchen equipment should be placed so that it can be used with minimum effort and movement. Generous storage space and heat-resistant working surfaces make for ease and speed. When the area is part of the living room it is sometimes effective to furnish it in a similar manner. If the cabinet building material is natural wood, it is often possible to buy range, refrigerator and sink units which harmonize with it, or separate units of stainless steel which can be installed as part of the cabinet work.

Bedrooms.—Quietness and privacy are obviously the first considerations but lighting (natural and artificial) and ventilation are also important. Built-in cupboards help to prevent clutter, and in warm climates venetian blinds and an adjoining terrace or balcony are desirable. It may be preferable to plan a bedroom as a bed-sitting room (especially if there is a separate space for dressing) and it should be possible to decorate it in a more individual style than is practicable in the common living areas.

Bath and Dressing Rooms.—If several people share the facilities it is sensible to separate the lavatory, bath and dressing space. Well-planned storage and airing cupboards (usually built-in) and good lighting, heating and ventilation are advantageous. Provision may also be made for such luxuries as a private sun-bathing deck or terrace, a reclining couch, a large plunge-type tub and a space to grow plants.

Storage Space.—The convenience of a house is greatly increased if each area has enough storage space for its own equipment, and thought should be given to bulky items like sewing machines, movie projectors and sports equipment. Adjustable shelves and partitions are often a great help, and, where the storage space is handled as part of the architecture, a whole or partial storage wall, built to order or made from portable units, and accessible from either side, will be found an efficient and compact arrangement.

Children's Rooms.—In families with several children and limited space, portable walls may be used to close off areas for sleep or study or where older and younger children may each entertain their own visitors. Young children need low cupboards for toys and clothing (adjustable units are the most practical) and windows low enough to look out of. Furnishing and decorating materials should be durable; some sort of warm flooring, such as linoleum, cork or some of the resilient plastic tiles, is better than cold materials like ceramic and asphalt tiling. Ceiling and wall lights are safer than table and floor lamps. As a rule children prefer clear colours, neither dark nor pastel, and red and blue are favourites. Slate and bulletin boards are useful in a young child's room.

In the general living areas the furniture should also be sturdy and easy to clean. (G. A. E.)

B. Light and Colour

The planning of colour schemes is one of the most important aspects of interior decoration, but one which often fails to provide full satisfaction; the most common difficulty is failure to appreciate the fact that the appearance of a coloured surface depends on the nature of the light that illuminates it. All kinds of light source, including daylight, which are normally used to light interiors have different effects on colours; and this is true even of different kinds of sources whose lighted appearance may seem to be identical in colour.

A blue surface looks blue because it reflects blue light (if any is present) but absorbs other colours of light; similarly a yellow surface reflects yellow light but absorbs other colours of light; and so on with other coloured surfaces. It follows that if all colours of surface are to be seen at the same time in their true colour relationship, then the illuminant used must contain all colours of light at equal strength. Such an illuminant will appear white (*i.e.*, uncoloured). If the illuminant contains all colours of light but not at equal strength, surface colours take on a different appearance; if, for example, green light is dominant, green surfaces will be emphasized; if green light is weak or absent, green surfaces will appear dull and greyed.

1. Kinds of Light.—Daylight from a lightly overcast north sky (in the northern hemisphere) contains all colours of light in about equal proportion and is the "truest" of all lights for revealing colour, but daylight is very variable. A blue sky will emphasize the "cool" colours—the blues and greens—and will tend to weaken the "warm" colours, the yellows and reds. Noon sunlight has a slightly "warmer" effect on colours than north sky light, and the golden sunlight of the late afternoon brings out reds and yellows very strongly at the expense of blues and greens.

Decorative colours can of course be chosen to offset to some extent the kind of daylight most often available. In climates where many months of cold cloudy weather are to be expected, and for rooms into which sunlight seldom or never penetrates, it may be desirable to decorate in predominantly warm colours, and conversely for hot sunny climates cool colours are usually chosen. Tinted translucent window curtains or tinted venetian blinds may be used on occasions to add extra apparent warmth (or coolness) to the light entering the room, but since such devices work by extracting unwanted cool (or warm) colours from the light, they may spoil the appearance of room decorations chosen without this possibility in mind.

In comparison with daylight, ordinary incandescent lamp bulbs give an excess of red/yellow light and a deficiency of blues. Warm decoration colours are therefore emphasized and cool colours dulled. Various coloured bulbs are available to produce overall warmer or cooler effects, but here again the process is one of extraction which reduces the total amount of light available. The "daylight blue" lamp, for example, has a light-blue bulb which absorbs the excess yellow/red light generated by the filament; but it cannot change other colours of light into blue. Thus, although the resultant light given by the lamp appears white and somewhat similar to daylight, there is still in fact a deficiency of blue light, and cool decorative colours therefore still show weakly. Coloured shades or tinted glassware surrounding the lamp modify the colour of the light by a similar process of extraction.

Fluorescent lamps produce light with a balance of component colours of light generally quite different from that of daylight or incandescent lamp light, though there are varieties made especially to simulate north-sky daylight and incandescent lamp light. The first fluorescent lamps, which were made primarily to produce light at highest possible efficiency, overemphasized decorative colours in the yellow and green parts of the spectrum but were very weak on reds and blues, and it was therefore a matter of some difficulty to plan successful decorative schemes for them. In the newer types of high-efficiency lamps the colour-rendering has been somewhat improved and there are now also other types (sometimes referred to as the "deluxe" types) in which some of the luminous efficiency is sacrificed in order to obtain better colour rendering, especially at the red end of the spectrum. With the wide range now available it can be claimed that there is a fluorescent lamp

colour suitable for any normal purpose and decorative scheme.

2. The Effects of Light on Colour.—There is no colour without light. Within practical limits, the stronger the light the greater one's appreciation of colour. Very strong colours are generally more suitable for dim than for strong lighting, and very strong lighting usually requires colours in pastel shades if they are not to become overpowering.

Except perhaps for those living in equatorial regions, a warm colour of light is preferred if the lighting is dim. The stronger the lighting, the more a cooler colour of light is preferred, but a cool light may be considered uncomfortably cheerless if there is not much of it present.

Since decorative schemes are normally to be seen both by daylight and by artificial light, colours should be selected for their appearance under both kinds of light and if possible under about the intensities of each kind of light that they are likely to receive. Under the two kinds of light, decorative schemes predominantly of a single colour are likely to change most in appearance; each individual colour of a multicolour scheme will also change, but since all the colour changes are likely to be in the same direction the over-all effect may not be materially altered.

Normally there is no reason, other than personal preference, why more than one colour of artificial light should not be used in the same interior. A room might be mainly fluorescent-lit, for example, but an incandescent lamp spotlighting a vase of flowers or other special feature will emphasize it partly by extra light intensity and partly by the change of colour; a similar effect for a dining recess could separate it from a kitchen almost as effectively as a room divider. (*See* also LIGHTING.)

(A. D. S. A.)

3. The Selection of a Colour Scheme.—Many considerations are involved in successful colour planning: the relationship between colour and light, mentioned above; physiological and psychological reactions to colours; the effect of colours on the apparent size and shape of rooms and furnishings; problems of upkeep; and, of course, personal preference. Most colour research has dealt with the scientific aspects rather than with the aesthetics of colour, yet both kinds of information are necessary to the interior designer.

A designer may draw on many sources for his ideas but nature is an obvious and inexhaustible source of supply. The subtle combinations of green and yellowish green in spring foliage seen against a clear blue, might well be adapted to an interior colour scheme, as might the ever-changing contrasts of red, yellow and dark green of early autumn, or the delicately graded hues of later autumn colouring. Colouring in nature is never uniform: at first glance a lawn or forest looks solidly green; closer study shows that it is composed of myriad shades and many other colours besides. It is found in practice that interiors which have some of this variety are likely to be more successful than those which rely on single notes of each colour. New colour combinations may also be suggested by paintings, although the artist's scheme must be treated carefully: colours which may be stimulating on canvas may be unsuccessful when used in much larger quantities and in different relationships. The colouring of boldly patterned fabrics, likewise, may form the basis of a colour scheme, but this too must be adapted with discretion. In short, while nature or art can directly inspire many fruitful ideas it cannot provide an infallible formula for success; but the study of nature and art bestows indirectly an even greater benefit, the gradual quickening of one's sensibilities.

Generally speaking, shades of yellow, orange and red are found to give an impression of warmth; conversely, blues and greens give the impression of coolness. This fact often influences the choice of decorative colour and gives rise to the terms "warm" and "cool" colours.

4. Colour Harmonies.—The greatest degree of harmony is attained by using related colours. A room might have a floor covered with a grayed, medium yellow rug or matting, a storage wall made of light birch paneling, one other wall of dark yellow-brown cypress, a fireplace of yellow-gray brick or stone, and furniture of both light and dark yellow-brown woods. Upholstering materials might include textured light neutral yellows, yellow-browns and brighter yellow leather, with various accessories in gold, brass and other yellow colour notes. However, some contrasting colour would probably be necessary, for example, a cool grayish-blue, green or white. Similarly, a basically neutral-coloured interior employing shades of white and gray in varied textures with accents of black looks well with a touch of strong, gay colour. Many other related colour schemes can be worked out by using colours that are next to each other on the colour wheel.

As a general rule, contrasting colour schemes, defined here as those which emphasize shades of more than one of the following—blue, yellow, red (the primary colours), black and white—are most satisfactory when one colour is used in the largest areas and repeated in various tones (degrees of lightness and darkness) in other parts of the room. The other colour or colours should also be used more than once to avoid a spotted effect.

5. The Use of Colour.—Large expanses of bright colour should be avoided since they cause eye fatigue, though in smaller quantities they can be pleasantly stimulating. One of the commonest errors in choosing paint for walls is to get colours that are too bright because colours in small samples look much duller and paler than when painted over large areas.

If some measure of unity is desired throughout the house, it can be achieved by making floors or walls or windows the same colour throughout, or by using the same colours differently related in adjoining areas. For example, the colour of a wall in one area might be repeated in the upholstery or carpeting in the adjoining one. Interchangeable furnishings make colour schemes more flexible and are also economical.

Colour can be used to emphasize or minimize architectural characteristics. A large room, for example, can be made to seem even larger by the use of cool and light colours such as blues and greens; warm dark colours reduce its apparent size. Similarly, the walls in a small room may be made to seem farther apart if they are cool and light; if dark and warm in colour, they may seem either cozy or oppressively close together. Similarly, ceilings look higher when they are painted in light colours, lower when they are painted in dark ones. In practice the needs of a room often conflict, for example if a small cold, north-facing room is to be painted a warm colour, like yellow, the colours must be kept light in value or they will make the room seem smaller. If cool colours are used on the walls or floors to provide an illusion of spaciousness, some warmth of colour might be provided by paintings or other accessories or by upholstered furnishings that are relatively small. When a desired colour is not well suited to the size or orientation of a room, choice of companion colours may provide a solution.

Unpleasant irregularities, such as poorly spaced window and door openings, may be minimized by painting the woodwork the same colour as the walls and by using draperies that are similar to the walls in colour effect.

Furniture which is unattractive in shape or too bulky can be made less obvious by making it the same colour as the wall or the same tone in a different colour. Strongly contrasting tones will emphasize sizes and shapes.

Colours of medium tone are the most practical: most soil and foot marks show readily on very light colours, while dust and lint are most evident on black or dark colours. It is especially important to remember this when choosing colours for floors and upholstery, which both have very hard wear.

The function of a room also affects the choice of colour to some extent. Generally speaking, strong contrasting colours and tones suggest activity, and closely related colours and tones suggest rest. An area such as a playroom might be designed with basic colours that offset the noise and confusion and enough bright contrasts to be in keeping with the lively atmosphere. Sharp contrasts in tone must be avoided for close work. The extreme relationship of white and black gives a brightness ratio of 28 to 1 (since white may reflect 85% of light and black only 3%) whereas lighting experts recommend ratios ranging from 3 to 1, which is preferred, to 10 to 1. These ratios relate not to details but to walls, draperies, floors, ceilings, desk or work counter surfaces and other major areas within line of vision of a worker.

Precise specifications cannot be laid down for the colour rela-

tionship of floor, walls and ceilings. In the most common scheme the floor is darkest in value, not very bright and usually somewhat warm in effect; walls are a little lighter than the floor and often somewhat neutral and warm; the ceiling is the lightest of all and is usually completely neutral in hue or just slightly tinted. It may be significant that a similar relationship normally exists in natural surroundings between the earth, the vegetation and the sky. It has been shown how other arrangements are employed to modify the apparent shape of rooms, to harmonize furnishings, and to cater to personal preferences.

Finally, thought must be given to the order in which materials for a new decorative scheme are acquired. The most permanent and expensive item should always be purchased first, especially if it may be difficult to find. Usually this is the rug, or perhaps the draperies, or even a very special wallpaper. Other fabrics, too, should be chosen before the colour of the paint, because paint can easily be mixed to harmonize with them, whereas the selection of fabrics in a certain colour may be greatly limited. In certain other interiors architectural materials, such as exposed wood and stone, will have to be given first consideration and will continue to influence the other choices of colour. Lastly, light and colour planning should always be done together. *See* also COLOUR.

C. SURFACE TREATMENTS

1. Walls.—*Permanent Finishes.*—The same materials that are used on the outside of a house—brick, stone, wood, glass and cement blocks—may be used on interior walls to give a unified character to the building. Although the original installation cost of such materials may be high, care and upkeep are easy and cheap. However, they do not allow changes in decoration to be made easily.

In the past wood paneling was a favourite means of decoration and also provided much needed insulation. The intricately fitted pieces of recessed or raised sections and moldings of solid wood paneling required skilled hand craftsmanship. Contemporary interior wood paneling usually consists of large plywood sheets which can be installed with a minimum of time, labour and skill. Although a choice hardwood, such as mahogany or walnut, may be used for the surface veneer or lamination, the core and inside sections can be cheaper soft woods which are durable and in greater supply.

Other materials that are relatively permanent and durable include some that are more often considered for floors only, such as linoleum (either in sheets or tiles) and cork, plastic, ceramic or marble tiles. However, ceramic and marble, as well as other rock substances and glass, are used for making mosaics, a form of surface decoration which has been used for walls, floors and to a lesser extent ceilings, for thousands of years. At mid-20th century renewed interest in mosaic work was seen, but it remains an expensive and specialized technique. (*See* MOSAIC.)

Flexible walls are being used in increasing number. Panels of glass fibre or other transluscent forms of glass give privacy without cutting off light, while folding or roll-away units are made with fabric, split bamboo, matchstick or hinged wood panels. Storage walls may be of wood finished to harmonize with other woods in the interior or of fibreboard or plastic on metal frames.

Painted Walls.—The commonest and least expensive wall finish is paint, which can be easily applied and changed. Textured paints may be used where irregularities in surface need to be camouflaged. Glossy or semiglossy paints forming hard smooth surfaces are desirable in areas that need frequent washing (nurseries, bathrooms, kitchens); otherwise, dull finishes are generally pleasanter.

The walls of a room may be painted in one colour, or one or two walls may be painted a lighter or darker tone of the basic colour, or even a contrasting colour. A contrasting wall changes the apparent proportions of a room and for that reason may be especially desirable in a square boxlike area. A contrasting wall colour is generally best used where there is an unbroken expanse of wall or in a niche or alcove that deserves emphasis.

Woodwork and doors may be painted with a colour contrasting to the wall colour, but generally a pleasanter, more unified effect is achieved when the wood trim is painted the same colour as, or one that is only slightly darker or lighter in value than, the walls. Where the size and shape of the window and door openings are irregular or ill-proportioned, it is important that they should match the walls.

Although the approximate colour of walls must be decided before furnishing materials are chosen, the paint should be purchased after the fabrics because it can then be mixed to harmonize exactly with them. As a rule it is desirable to plan background colours that are somewhat lighter or more neutral than the colours of the furnishings fabrics. If possible, a portion of the wall should be painted, allowed to dry, and examined both in the daytime and at night under artificial light before the final colour decision is made. It is unwise to make a final colour choice from a tiny paint sample.

Pictorial designs or murals may be painted directly on plastered walls, using a fresco technique, or they may be painted with oil colors on canvas which is then stretched on the wall surface. (*See* also PAINT.)

Wallpaper.—Wallpaper was used as early as 200 B.C. by the Chinese who painted designs by hand on rectangular pieces of rice paper about 12 by 16 in. in size. Chinese papers were first imported into England and France in the 16th century, but hanging of these papers was made difficult by their small size and by the casual matching of patterns from one piece to another. In a late 16th-century French work is described a "guild of painters and paper hangers," *dominotiers*. About 1688 a master dominotier, Jean Papillon, invented a continuous matching design in wallpaper strips, and a method of producing these strips in continuous rolls was invented in France in 1798. Scenic papers accompanied by a numbered chart and special instructions for matching the strips together were next developed.

Flat-headed nails were first used to hang paper, but later in both France and England paste was used. Ready pasted wallpaper was developed in the mid-20th century.

Most modern inexpensive and medium-priced papers are machine-printed by the roller or cylinder process. A greater variety of special colour and design effects are made possible by a second method of printing, the silk process, which requires more hand labour and results in costlier paper. Hand-blocked papers are also available to a limited extent. (For the history of wallpapers *see* further WALLPAPER.)

With the great variety of wallpapers available, it is possible to achieve almost any effect. Since patterned walls limit the number of paintings, accessories and patterned fabrics that can be used effectively, a person to whom accessories are important should choose plain or only slightly patterned paper. In a room with no special accessories, or with no focal point such as a fireplace or a fine view from a large window, one wall might be papered with a fine distinctive design. Some of the difficulties of using patterned paper as a background for furniture were avoided by the 18th-century interior designers who generally used paper only on the upper wall above a plain-coloured painted dado.

Some wallpapers have co-ordinated matching fabrics for use as draperies or slipcovers in the same room or in adjoining areas to be seen against plain-coloured walls. It is important to consider size or scale of wallpaper design in relation to size of room. Large designs in bold colours are suitable only for spacious areas, small designs for small spaces.

However, designs that are small but so close together as to form a general over-all effect of texture may be equally effective in large and small areas. Wallpapers with strong contrasts of dark and light, and those which give a three-dimensional effect, should perhaps be avoided, since they will violate the natural flatness of the wall.

Wall Fabrics.—Fabrics as wall covering have an even longer history than does wallpaper, which, in fact, was originally an inexpensive substitute for fabric hangings. Almost any kind of cloth may be used on walls, and it may be draped in folds, stretched over panels or pasted directly on the wall. Paneled walls of silk damask, velvet and brocade were widely used during the Renaissance and 18th century in the palaces of Europe, while cotton fabrics were used in modest provincial homes. Tapestries were hung freely from walls or were stretched over panels. Leather was

used in similar ways, particularly in Spain.

In contemporary times the fabrics most commonly used for wall covering are durable ones such as canvas, burlap, denim, chintz and gingham, which may be applied directly to a wall. Grasscloth, which is more sheer, may be purchased already glued to a paper backing so that it may be hung like ordinary wallpaper, and other sheer materials must be handled similarly.

Plastic or plastic-coated fabrics may also be used. They are more durable and easier to clean than either untreated fabric or paper.

2. Fireplaces.—Although a fireplace is often no longer necessary for warmth, it continues to serve as a pleasant focal point for group gatherings and as a symbol of warmth and hospitality. Fireplace materials and design are largely architectural matters. Usually the fireplace is an integral part of a wall. Traditionally it was centred on a major unbroken wall space, giving it maximum effectiveness as a source of warmth. Often the central position suggested a formally balanced group of furniture on either side. In contemporary homes it may be part of the only thick and solid wall in an interior which otherwise has window walls and screen partitions. It may divide two areas and be accessible from both sides, although this arrangement has some practical drawbacks. In other cases the fireplace may be like a piece of furniture—a portable unit placed in a central location, accessible from all sides, with a hood and chimney above.

Special furnishings are needed to prevent the fireplace opening from being a stark, black, gaping hole when the fire is not lighted. Brass, copper and other metals which catch highlights from the fire are attractive both as hearth fixtures and as general accessories. (*See* also CHIMNEY PIECE; FIREPLACE FURNISHINGS.)

3. Windows.—The decoration of windows and doors should be closely co-ordinated with that of the solid wall areas. Light, privacy, outside view, ventilation, traffic through the room, the size and shape of the openings in relation to each other and to the total architectural unit, and, finally, purely personal preferences, are all important considerations.

Because outside light and temperature change both daily and seasonally, as do the needs of the house occupants, flexibility is one of the most important requirements for window treatment. Durability, including resistance to sun and moisture, and ease of maintenance are also considerations.

Shades, Blinds and Shutters.—Roller shades are the device most commonly used to ensure privacy and control of daylight. These can be obtained in varying degrees of opaqueness as well as a variety of colours. Pyroxylin-impregnated cotton shades, durable, washable and fire- and weather-resistant, are usually preferred. The disadvantage of roller shades is that when they are pulled they block out the best light, that from the top of the window; they also cut off ventilation. Bamboo and matchstick shades may be hung in the same way as roller shades or like draw draperies. Their special advantage is that they allow some ventilation, but they do not give complete privacy. In addition, many attractive colour combinations of woven fabrics, wood slats and decorative textured yarns may be used as window or door shades, controlled from a rolled position above the window or treated as draw draperies.

Venetian blinds, consisting of horizontal slats supported by tapes and controlled by cords, provide a maximum of light control and privacy without loss of ventilation, and the pattern of light they produce may be decoratively pleasing; however, they are tedious to clean. Vertical slat blinds are available in a variety of fabrics and colours. Though rayon or other man-made fibres are most commonly used, plastic strips are available for use in such areas as bathrooms and kitchens. The strips may be removed for cleaning or laundering.

Shutters provide a relatively permanent way of controlling light and privacy from within. Usually they seem to be part of the architectural detail of an interior.

Curtains and Draperies.—The purposes of curtains and draperies are varied and their selection is one of the most exacting and important tasks in interior decoration. Their practical functions include absorption of sound and control of privacy, light and temperature. In their decorative functions, curtains and draperies serve to soften hard structural lines of openings; they may provide an inconspicuous transition from indoors to the outside; and they may have distinctive colour and pattern that is important in the interior decorating plan. Although curtains and draperies are generally confined to windows they are sometimes used in doorways, as partitions or on walls for camouflage or acoustical purposes.

Fabric.—Some knowledge of textile fibres and weaves is helpful in making a wise selection of curtain or drapery material. No fabric is perfect for all purposes. The natural fibres, most familiar to consumers, include cotton, flax, silk and wool.

Cotton can be made into many kinds of materials, from canvas and heavy hopsacking to sheer net and gauze. Unless it has been given special finish, cotton stains and soils readily, but it is likewise easily laundered. Mercerizing increases the strength and lustre of cotton cloth, and, in addition, cotton fabrics may be made crease resistant, water- and mildew-repellent, and fire- and flame-proof. Glazed chintz is cotton fabric that has been given a permanent glaze by the addition of resins.

Flax is strong, durable and nonresilient. The fabric into which it is woven is known as linen and is fresh, crisp and easily laundered. Linen fabrics range from the sheerest curtaining to thick drapery material. Jute, a fibre similar to flax but less widely used, is often combined with flax, cotton or wool. When used alone, as in burlap, it has an attractive, rough texture but it deteriorates in sunlight and, when dyed, its colour fades quickly in a strong light.

Wool drapes well and does not soil readily. It can be dyed to produce beautiful colours and is an excellent soundproofing material as well as insulator. Its disadvantages include vulnerability to moths, mildew, strong sunlight and moisture; it is therefore unsuited to the tropics and, in other areas, drapes are usually lined to protect them from the sun. Often wool is combined with cotton in uneven twill-weave constructions that keep the wool yarns mostly on the surface and the cotton ones on the back, a device which lessens cost and increases serviceability.

Silk is used for the most luxurious drapery materials—for example, velvets, brocades, taffetas and fine damasks—or sometimes for less formal materials. It takes dyes well and drapes beautifully but it is expensive and not highly resistant to the sun. As with woolen draperies, a lining will lessen considerably the deterioration caused by sunlight.

Of the ever-increasing number of man-made fibres available for use in textiles, some are so new that little is known about their long-term serviceability. Much has yet to be learned about fabrics made of blends of two or more man-made fibres and of combinations of natural and man-made fibres. It is important that users read and observe with care the directions for maintenance of these fabrics given on labels. Following is a brief list of some of the man-made fibres commonly used in curtain and drapery fabrics.

Orlon is highly resistant to sunlight deterioration and to gas-fading. It drapes well and can be produced in lightweight and thick fabrics.

Nylon possesses great strength, elasticity and resilience and is easy to clean and dry. It is not attacked by moths or mildew and although it is not highly resistant to sunlight, it gives satisfactory service if directions are followed. Nylon curtaining is available in white and pastel colours, in fine ninons or marquisettes, some decorated with embroidery or flock printing.

Dacron has been used widely because it preserves its original size and crispness through extreme changes of humidity. Lengthwise Dacron yarns are sometimes combined with other yarns to eliminate sagging or stretching under humid conditions. Much glass curtaining is made of pure Dacron.

Dynel, made into a wide range of fabrics, is resistant to moths, mildew and flame, and does not shrink or stretch. It washes well and often is blended with other fibres.

Velon fabrics absorb little water and retain their crispness after repeated laundering.

Acetate is available in several forms. Fortisan acetate is durable and strong and may be woven into sheer fabrics. Chromspun and Celaperm, solution-dyed acetates, possess a "locked-in" colour which resists fading by sunlight and gases.

Fiberglas is made into curtain and drapery fabrics in a wide range of textures and weights. It is resistant to sun deterioration, mildew, moths and fire and is very easily cleaned. Conventional fabrics filter light through spaces between the yarns; Fiberglas yarns diffuse the light and themselves transmit it, the effect being softened and diffracted.

Plastic vinylite films are inexpensive draperies. They are resistent to moisture and soil but are affected by extremes of temperature.

Bamboo and split-wood materials, sometimes called matchstick, can be used in place of textile drapery. (*See* above, *Shades, Blinds and Shutters.*)

Colour.—Glass curtains are usually white, cream, beige or very light pastel in colour, because outside light needs to be filtered through them. White glass curtains do least to change the colour of natural light and give a fresh, airy quality to an interior. Light colours, however, may be used to give special light effects: very light blue or cool green tints or gray give coolness, while beige, cream, yellow or orange tints give warmth to an interior. The exterior effect of the curtain colour also requires consideration; usually it is well to have similar colours on all windows facing the same direction.

Since windows are a part of the wall background, drapery colours similar to the colour of the rest of the wall area give maximum unity to an interior, an effect especially to be desired in small rooms and in areas that have many fine accessories as a part of the decor. Treatment of windows as part of a quiet wall background also is called for in interiors that have especially fine outside views or those having distinguished architectural details and materials. In situations where the window treatment is to be the principal decorative feature of an interior, wall tones and other furnishings may be planned to harmonize with them.

The choice between plain or patterned fabric also depends upon the structure of the room and any existing decoration. Where the walls or floors are figured, or where many accessories are desired, plain fabrics may well be the best solution—though in some rooms, multicoloured patterned draperies may give unity to all other elements and add special interest. The scale of the pattern should be related to the size of the interior and to the furniture. Large-patterned fabrics can be used effectively only in relatively large areas and at windows where they can hang in long folds, usually to the floor. Smaller designs are usually more versatile. Finally, for a really satisfactory decorative scheme, the over-all effect should be in keeping with the function of the area and the characters of its occupants.

In considering drapery fabric, a sample should be hung at the window in folds so that its effect on the light, and the effect of light upon its colours, may be observed. Also, the sample should be held against other furnishings in the room to see if its colours and patterns harmonize with them.

Hanging Draperies.—The way in which curtains and draperies are hung affects the apparent size and shape of the openings and wall areas, as well as the sense of openness or warmth.

In general, draperies are most effective when they hang in straight folds, covering the window frame and starting and stopping at structural points. They may hang from the top of the window frame or from the ceiling and extend to the floor (actually about ½ in. above the floor) or to the bottom of the window frame. Sometimes because of special considerations, such as radiators or shelves under windows, they may need to extend only to the window sill, but the longer lengths are usually more desirable, especially if the fabric is bulky or is hung from the ceiling.

The width of draperies needs to be generous, usually from 2 to 2½ times as wide as the window area to be covered. If the fabric is sheer, a width three times the window area is better.

A group of windows can be unified by a cornice or valance. A cornice is a horizontal band of wood or fabric-covered wood placed across the tops of windows to cover curtain and drapery edges and rods. A valance is similar but is made of a strip of fabric or fabric-covered wood.

An effect of greater length is created by hanging the valance above the window casing, thus increasing actual length of drapery as well as height of window. A short drapery can be used like a valance at the top of a window above interior louvers or shutters.

Where windows meet in a corner, an effective treatment is to hang draperies only at the side of each window where it joins the wall, so that when they are drawn they will meet at the corner structural line. For greater privacy, corner windows could have sheer draperies or curtains hung over the entire glass area, with stationary draperies at the far sides. A large picture window is usually most effectively treated by simple draw draperies that can hang over the wall on either side of the window, thus giving maximum openness, or that can be drawn over part or all of the glass. It is important that the fabric hang in generous folds.

Windows of different width in one room can be made to look uniform by extending some draperies beyond the window casings. Windows of varying height in the same room are given unity by hanging a valance from the ceiling to the top of the window casing. A high narrow window looks wider if the drapery covers the wall a little on each side, the extent of the extra drapery depending on the proportions of the wall spaces. Similarly, if the window is overly low and wide, an opposite effect is achieved if the drapery is close to the window and allowed to hang to the floor. If the ceiling is low, it is better to omit valances and to hang draperies in straight vertical folds from ceiling to floor. Several windows separated by small wall spaces may be treated as a single unit and the whole area hung with a ceiling-to-floor drapery with valance extending across the top; if the drapery starts at the top of the window frame, the valance may be omitted.

Glassed doors, or French doors, are often hung with draperies or curtained with a lightweight fabric held in place by rods at both top and bottom. If the doors open to the exterior, they may be covered entirely by draperies. Crane-type door fixtures, which permit the draperies to be swung free from the doors, are available.

Draperies may be hung for decorative purposes, as a sound absorber or to camouflage an ugly wall even when there are no openings in it. They may also act as a partition, the most convenient form being a draw drapery hung from a ceiling track.

Hanging Curtains.—Curtains are hung inside and close to the window frame and glass, and are short enough to clear the sill. When they are used as draperies, they are hung outside the frame and may extend to the bottom of the sill, or to the bottom of the window frame, or to within ½ in. of the floor. (*See* also CURTAIN; WINDOW.)

4. Doors.—A door that is much used for major traffic yet is closed most of the time may be treated simply as part of the solid wall background; *i.e.*, it may be painted the same colour as the wall or be of wood finished similarly to other wood surfaces in the room. A door that is never used may need to be removed; many old houses have unnecessary interior doors which take up valuable wall space when left open and give a cramped look to small rooms when closed. If a door is needed for privacy, but there is limited space for the conventional swinging door, a hinged folding door, hinged shutters or sliding doors may be used. A door with adjustable louvers may suffice where an opening is needed for ventilation but privacy is required; furthermore, louvered doors may give a pleasantly decorative effect.

Glass doors are usually treated in much the same manner as windows. Glass curtains may be hung directly on the door casing itself, with rods at both top and bottom. Draw curtains or draw draperies generally are hung from the frame above the door with provision for drawing them to the side to give clearance when the door is opened. Occasionally, side draperies are used over the framework on each side of a glass door. Wherever door curtains or draperies are used, they should be integrated with the window and solid wall treatment of the interior. Glass doors that need no provision for privacy or light control may be left uncurtained.

Doors may serve special decorative purposes. There is traditional precedent for each of the following suggestions: a door may be painted a colour that contrasts sharply with the walls of a room, or it may have decorative designs painted on it; in either case the colours should be related to the general interior decor and the door placement be such that it becomes a pleasant design accent. Coloured glass panels in a door may serve a similar colour and

design accent purpose. Leather, either plain or stamped, may be mounted or nailed onto a door surface to give a richly handsome texture and colour. Fabrics or plastics also may be used to cover a whole door or its inside panels. An inset of a mosaic panel or a painting or a piece of wood or metal sculpture may be used for decorative purposes on a focally located door. Japanese doors with a geometric latticework pattern made of strips of wood backed with paper or fabric may be used as sliding partitions in an interior area. (*See* also DOOR.)

5. Floors.—Durability and ease of upkeep are vitally important considerations in selection of floors and floor coverings, but since floors also contribute importantly to the beauty of an area their appearance cannot be neglected. The amount of emphasis to give floors depends upon the total decorating scheme. Usually it is desirable to be fairly conservative and to provide a floor surface that is restful in effect, not only because of the relatively high cost and long life of floor coverings but also because the floor needs to appear stable. Yet in an otherwise plain room with few distinguished characteristics, a handsome patterned rug, such as an oriental or other handmade rug, may be the most important design element.

Floorings.—Inside floors and outside living terraces may be handled as one continuous floor, covered with such materials as brick, stone or ceramic tile, for a durable flooring and a maximum degree of unity. These materials, however, are costly to install and give a surface that is noisy and hard to stand on. Other flooring materials, such as linoleum, rubber tile and a variety of plastic-type tiles, which may be used on inside floors requiring frequent cleaning, are less costly and more resilient, though they are also less distinguished in appearance. Cork tile is resilient, durable and attractive for general living areas; it is also pleasantly warm and comfortable and so is suitable for family or playrooms. Wood, of course, continues to be one of the most generally useful and beautiful floor materials. No material, however, is completely satisfactory for all kinds of situations.

Rugs and Carpets.—Generally some kind of additional floor covering is desirable to give softness of texture in at least a few areas of a house. Choice of carpeting or rugs depends upon many factors. Wall-to-wall carpeting hides nondescript floors and gives maximum spaciousness to an area but, unless that area is entirely regular in shape, wall-to-wall carpeting cannot be turned for even wearing. Furthermore, such carpeting is costly, especially if made of high-quality materials. A rug that is seven or eight inches smaller than the room dimensions gives almost the same effect as wall-to-wall carpeting and can be turned easily. Use of rug pad or cushion lengthens the life of a rug or carpet.

Smaller rugs may be used to unify furniture groupings and to provide colour and softness of texture in areas having fine-quality floors as well as in areas that need to be uncarpeted for special activities. For example, in a living-dining area used by an active family with young children it may be desirable to leave the dining space uncarpeted but to place an area rug in the living room part of the space to give a pleasant textural quality and absorb sound as well as to unify the furniture arrangement. In some contemporary homes of open plan with very few interior wall partitions, rugs may be used to define activity areas.

Small rugs tend to give a sense of coziness. They need to be large enough, however, to be in scale with the furnishings and the over-all room size, although several small rugs can be grouped together to give the appearance of a larger one. It is usually desirable to arrange rugs parallel with the structural lines of a room. They should have a rubberized backing, or separate rug anchoring material should be placed under them.

Well-designed rug patterns are much like well-designed patterns in any fabric or wallpaper. First, they are relatively flat in appearance. Designs which give a sense of three-dimensional depth, whether in geometric shapes or natural forms, produce an unstable and distracting effect, as do very strong contrasts of dark and light colours. Fine oriental carpets set a high standard of design in patterned rugs; although most of them have intricate patterns in many colours, the designs are flat and non-naturalistic in effect.

A number of contemporary artist craftsmen, particularly in the Scandinavian countries, are designing and making beautiful rugs for floor or wall coverings. Hand-braided and hooked rugs, which have a long history, continue to be a handicraft of importance to a limited number of people. These handmade rugs can be used to give individuality to homes where they are in keeping with the decorating plan. Machine-produced rugs and carpets, however, must supply the major decorating needs.

Figured rugs or rugs with some over-all mixture of colour do not show soil so readily as plain colours do, and for that reason are especially desirable for hallways and dining areas. Medium colours, neither very dark nor very light, are good for the same reason. A plain coloured rug that has some variation in the texture, such as twisted yarns for the pile or an irregular length of pile, is easier to care for than is a smooth one.

The effect of different colours of floors on the size of an area is discussed in the section on *Light and Colour*, above.

To make a wise selection of carpeting from the wide variety available on the market it is important to have some knowledge of fibres and construction techniques used in their manufacture. These are discussed at some length in the article CARPET MANUFACTURE. Types of rugs and their designs are discussed in RUG AND CARPET. (*See* also FLOOR.)

6. Ceilings.—Although ceilings in most 20th-century homes are given little thought in either building or decorating, they may play an important part in establishing the character of interiors. High ceilings may give a feeling of openness, airiness, spacious dignity or unpleasant vastness of space; low ceilings may give a feeling of coziness and intimacy, informality, or crowding and oppressive weight. Where either unpleasant extreme is present, the interior designer can create optical illusions of change of height through change of paint colour or by means of various structural and lighting devices.

In the too-high room a lowered ceiling panel sometimes may be used effectively. In a large room, only one area may have the lowered ceiling and the space between the upper and lower ceilings may be used for installation of indirect lighting. Sometimes a lowered ceiling may be made of translucent glass or plastic with lighting installed above, giving excellent, even, general illumination. Warm dark colours of paint or wood or patterned paper may be used to make a ceiling look lower. When this is done, it is necessary to use lighting fixtures that direct the light down or to place a light-reflecting disk above the fixture, since dark colours absorb a large amount of light.

Not so much can be done for the too-low ceiling, except in terms of optical illusion with colour, line and scale of furnishings. Painting the ceiling a very light, cool colour such as blue-white, and using long draperies without horizontal breaks, and furniture that is relatively low and light, help in obtaining a feeling of spaciousness.

Skylights are useful in interior areas that get little light, and they give a visual extension of space. Artificial illumination may be used above the skylight at night to provide a general glow of light. Coved ceilings give a pleasant curved transitional line between ceiling and walls and provide an excellent place to install indirect lighting.

Exposed ceiling beams give a substantial quality to flat ceilings as well as to those which follow the line of a sloping roof. Beams of fine-quality wood well fitted together can produce a ceiling design that may be the dominant feature in an interior, establishing the character of the whole decorating scheme. It need not necessarily be rustic in effect.

Ceilings may be covered with porous materials that improve the acoustics of an interior. This is especially important for areas where there is considerable noise and where there may not be many fabrics or other soft textures that absorb sound.

See also CEILING.

D. FURNITURE

1. Selection.—Obviously the first considerations in furniture selection are comfort and suitability. Yet these are not always easy to achieve. With sitting pieces there is the problem of providing enough variety in height and depth of seat to accommodate people of different size. Furthermore, no chair is comfortable for

very long periods of time, and frequent changes of position must be made. This would suggest that closely matched sets or suites of furniture are less desirable than varied pieces individually chosen for the proportions of the family. The design of various pieces of furniture should be compatible in general character, however. For example, one home may have a living area that has an informal, casual, almost rustic character, while another may have rooms with a sense of polished elegance. Both may be comfortable and suited to use.

Successful combinations of contemporary and period styles of furniture depend upon this compatibility: the factors to note are texture, weight or scale and line. Early American Colonial pieces have been used effectively with simple, sturdy, informal contemporary furniture, just as the elegant French and Italian 18th-century styles have been well used with some more polished, sophisticated-looking modern ones. Likewise, dark and light natural woods, painted pieces and metals may be used in the same room or area if they are basically similar in line, scale and texture.

Adaptability is an important consideration. Chests which may be used equally well in living, dining or sleeping areas are more economical than single-purpose chests. Study or bedroom chairs that harmonize with those in the living and dining areas can be used in those areas when needed. Modular furniture units, made in storage and desk pieces as well as sectional sofas and chairs with separate but co-ordinated footstools or ottomans, have a very wide range of use.

In small living quarters double-duty furniture is especially helpful. Small low chests may be used to replace end tables. Coffee tables with extra shelves or drawers provide valuable storage space. A dining or work table that is hinged to a wall and may be lowered for use and raised when not in use is a saver of floor space. Sliding or hinged, folding cupboard doors require less space than do full swinging doors.

Many fabric and wood finishes have been developed that are resistant to dirt and wear, an important consideration in selecting dining and coffee tables, and sitting pieces in much-used areas. Because the greatest amount of wear on upholstered furniture occurs on the arms, many pieces are designed with wooden arms and upholstery only on the body of the chair.

2. Arrangement.—Convenience is the first consideration in furniture arrangement, and for its achievement two kinds of information are needed: (1) activities that will take place in the area and (2) space needed for those activities.

Daily activities need first consideration, and furniture should be so grouped that a minimum of shift is needed. A room that is disarranged most of the time is one that was not arranged for convenience in the first place.

It is desirable to separate the kinds of activities in a room. For example, in a living room there may be a relatively small quiet conversation grouping, a place for desk and book shelves nearby, and piano and game table farther removed at one end or in a separate alcove or L. If possible, major traffic should not be routed through an activity area—especially the conversation grouping.

The "arc of conversation" or the maximum distance at which people can converse with comfort is approximately eight feet. In a large area, a couch or chairs may be placed toward the centre of the room at right angles to the wall in an L arrangement to create an intimate group and some separation from other activities. In a small room, one end or a portion of a side wall and an end wall may be used for such a grouping. In small rooms the doors often are so placed that it is difficult to contrive any conversation grouping unbroken by a major traffic lane. In this case, sometimes a low room divider (book shelves or other storage unit, or even a narrow table) may be used to direct flow of traffic and provide a pocket of uninterrupted space in a room.

Chairs and couches need table or other flat surface space near at hand for ash trays, magazines, etc. Good light is also important. Isolated chairs have little use in living areas except as additional accommodation for unusually large groups; small folding tables that may be opened and set up near pairs of chairs may be provided.

Besides the eight-foot conversation arc, a number of other dimensions need to be kept in mind in arranging furniture. The distance between coffee table and couch should be a little over a foot, to allow for knee room yet not exceed the distance for comfortable reach. Each person needs about two feet of space at a dining table, the host eight inches to a foot more. Passage space, whether between dining chairs and wall to accommodate serving, between counter and table in a kitchen or between bed and dressing space, needs to be planned with the utmost care. Three to four feet is generally needed, depending upon the number and size of people who will use it and the heights of the furnishings or walls.

Traditionally in most European and American homes the principal pieces of furniture were placed around the edges of rooms. This continues to be a satisfactory practice in some situations, particularly in very small rooms. However, in many contemporary homes there is little solid wall space because outside walls may be composed almost entirely of windows and doors, and inside partitions may be movable panels or storage walls. In such situations the large furniture may be used to divide the room into different zones, but whether it occupies the centre or the edges of the room it should be placed either parallel or at right angles to the walls. This is not only the most satisfactory arrangement visually but is also space-saving. Smaller pieces of furniture and those which are circular or irregular in shape generally may be deployed in a variety of positions. Lighter, open pieces of furniture can be used effectively against window walls, whereas solid pieces often look clumsy there. Some unfilled space should be left in every room or area to accommodate people and additional activities as well as to provide a sense of openness.

A design which provides a focal point and a number of subordinate points of interest is usually desirable. In living areas the focus is very often the fireplace, or perhaps a fine view, or it may shift from one focal point to another depending on the time of day or the season. When arranging a room it is helpful to sit and to stand in each part of it in order to ensure that the furniture groupings and the relationships between colour, light and texture will be satisfactory from every angle.

A balanced design might be defined as one in which there is a pleasant distribution of "visual weights," and it is not difficult to recognize a lack of balance in room arrangement. In the past, the principal pieces of furniture were placed in formally balanced groups that gave a sense of dignified stability and corresponded to the symmetry of the exterior. Most contemporary homes are basically asymmetric in architectural plan, and interiors, likewise, are often best handled in this fashion, though a mixture of styles in either setting can be successful.

Careful attention needs to be given to the relative sizes of the pieces, and also to their relative heights, since these make a linear pattern in a room. Once again, the most satisfactory arrangements in each case are those that avoid both extreme contrast and monotonous uniformity.

A sound way to plan an arrangement is to measure the floor space and to draw it to scale on a sheet of graph paper. All architectural details such as fireplace, doors, and windows, also need to be drawn to scale. Then, furniture pieces may be drawn in the same manner on a separate sheet and cut out so they can be moved about on top of the floor plan. Thus when a purchase is contemplated its effect on the room can be tested diagrammatically. The disadvantage of working with a flat plan is of course that it does not show the heights of furniture, and allowances must be made for this: for example, a coffee table may cover a relatively large amount of floor space yet actually not look very large because it is low, whereas a tall bookcase may cover a relatively small amount of floor space yet actually look heavy because of its height. If heights can be visualized, however, cut-outs can be of great help not only in buying the furniture but for trying out rearrangements of the various pieces without the labour of pushing them around. Distances between the pieces, paths for the traffic, and total composition can all be studied, and more efficient use of space and more effective composition are likely to result from such careful planning.

For a full discussion of FURNITURE DESIGN, *see* the article under that title. Furniture construction, quality, etc., are dealt with in FURNITURE MANUFACTURE. *See* also articles on individual fur-

niture pieces, as BED; CABINET FURNITURE; CHAIR AND SOFA; LAMP; SCREEN; TABLE.

E. Accessories

Accessories may be the most individual part of the furnishings. They include such items as paintings, books, rock collections, flower arrangements and ash trays. They may or may not serve a utilitarian purpose, but if they are to be worthy of inclusion in a home they need to have special significance for the persons living there and be so arranged as to enhance and enrich their surroundings. An interior without accessories is as noncommital as a hotel room, yet conversely too many can make a house seem cluttered or even museumlike.

Space must be provided for storage of accessories not in use. The Japanese traditionally exhibited only a minimum number of items at a time, and only those appropriate to the season. Certainly periodic change gives variety and freshness to interiors. Paintings, pieces of sculpture, ceramics or other such items give more pleasure when they are not displayed continuously. Books, on the other hand, may form a pleasant background which changes little except as they are used and additions are made.

In general, small accessories are difficult to use effectively in interior decoration. Miniature glass figures, for example, which may be exquisite in colour and the special hobby of a member of the family, will not even be noticed unless they are specially grouped and displayed with proper lighting.

It is difficult to generalize concerning proper location of accessories. It may be helpful to note focal points in a home, however, and to decide whether enrichment is needed at any of them. For example, the end of a hallway, the view through a doorway, the wall opposite a major seating space in a room or the view from bed would all suggest focal points at which accessories might be placed unless architectural detail or other furnishings are already prominent.

1. Pictures and Wall Hangings.—Pictures are usually not needed, nor are they effective, in rooms with patterned wallpaper. However, if the paper design is ordered and relatively quiet in effect, paintings may be used provided they have wide, plain-coloured mats or relatively wide frames or a scale of design in contrast to the wall pattern.

In hanging pictures, the total room composition needs to be considered. Pictures usually are best grouped with some furniture or architectural feature, their exact placement depending upon the size and shape of wall space, the furniture group and the height from which they are to be viewed. For example, pictures generally to be seen from a sitting position, as in a dining room, need to be lower than those to be viewed from a standing position in a hallway. In each case they should be at about eye level.

Small pictures are difficult to use effectively, though sometimes several may be grouped together. Lighting may be used to dramatize especially fine paintings.

Fabrics—tapestries, embroideries and special printed textiles—may be used like pictures for fine decorative effect. Large wall maps may serve decorative purposes only, or they may record family travels or be used to locate home town or country of guests. Enlarged photographs (particularly those taken by members of the family), grouped in a gallerylike arrangement or even covering a whole wall, are effective in decoration. Usually it is desirable to make sure the prints can be changed easily.

Mirrors used as an integral part of decorating need to be placed with much care. They are most effective where they reflect a pleasant view or lovely colours, a flower arrangement or some other accessory, or where they multiply the sparkle of metals or glass. Mirrors in conversation areas, however, can be disconcerting, and on some wall locations they seem to create an unpleasant void. (*See* also FRAME DESIGN.)

2. Plants and Flowers.—Plants provide a transition from inside to outside and soften severe structural lines. From a decorative point of view they may be chosen for variation of texture, line, size and shape of leaf or of the whole plant. However, it is also important to choose those which are suited to the room's particular light and humidity conditions. With plants as with other accessories, the larger ones are generally more effective in decorating, although small ones such as African violets may be grouped for a beautiful concentration of colour. Furthermore, position determines the size of plants to be used. A small plant is perfectly suited for a small end table, a larger plant or a tray with two or three small plants on it might be better for a medium-sized coffee table, while floor plants and those placed on large low chests need to be massive (three to six feet high).

Flower arrangements give a special charm to interiors, and because they must necessarily be changed frequently they encourage variety. (*See* also FLOWER ARRANGING.)

3. Special Hobbies and Collections.—Perhaps the most interesting and individual accessories are those which result from hobbies. The collector of fine glass and ceramics may choose items that can be enjoyed during regular meal service as well as in display. A well-lighted tank of tropical fish, with its fascinating colour and movement, is a hobby accessory that can be beautiful and highly interesting to the casual visitor as well as the hobbyist.

Many articles in the field of art also contain material relevant to interior decoration; *see* ANTIQUE; ENAMEL; GLASS; METALWORK, DECORATIVE; POTTERY AND PORCELAIN; SILVER AND GOLD WORK; WOODWORK, DECORATIVE. (G. A. E.)

II. COMMERCIAL INTERIORS

1. The Development of the Interior Design Profession.—Prior to World War II, most nonresidential interiors were either designed by the architects for the building or were not designed at all. More often than not, the building itself was at violent odds with its interior requirements: while the structure might be neoclassical, the functional requirements of the interiors were frequently modern in the extreme, so that either the interior spaces would match the exterior (and thus not function at all), or they would be made to function reasonably well—in which case the furnishings were not likely to match the style of the building.

This inherent conflict was resolved by a number of pioneer architects in the early part of the 20th century, although their example (contained in a few isolated buildings in Europe and the United States) did not have any great impact until after 1945. Long before World War II such men as Frank Lloyd Wright in America, Ludwig Mies van der Rohe, Walter Gropius and Marcel Breuer in Germany, Le Corbusier in France, and Alvar Aalto in Finland designed and built commercial and industrial structures in which exterior form and interior space were completely integrated, and both served the needs of 20th-century building programs. To achieve this complete integration, these architects discovered that they had to design the furniture as well as the actual building. As a result, almost all the really significant, early innovations in modern furniture design were carried out by architects such as those listed above.

The reason these architects had to design their own interiors down to lighting fixtures and doorknobs was obvious: the "interior decorators" of the time had no knowledge of modern architecture—or, if they had, they were generally out of sympathy with it. It took several decades to educate a new kind of professional: the interior designer, an expert consultant who understands and is in sympathy with modern architectural problems and solutions, and who is able to interpret the architect's and the client's intentions and translate these into functional and pleasant spaces in which to work.

To illustrate some of the ways in which interior design can help answer the needs of architect and client, it may be useful to describe two significant projects of the postwar years.

The first example, the General Motors Technical centre in Warren, Mich., designed by Eero Saarinen in 1949, is an illustration of complete design of structure and interiors by one person—the architect. The center is a complex of buildings remarkable not only for its enormous size but also for the painstaking attention to the smallest detail in every one of its thousands of working spaces. The "modular grid" of the exterior walls is echoed in the "modular grid" of interior partitions and ceiling systems; the elegance of exterior detail and finish is carried all the way inside and is found there in such seemingly unimportant details as directional signs,

lettering, elevator pushbuttons, clocks and even chairs and tables designed by the architect. Saarinen frequently said that a good piece of architecture had to be "all of one thing"; in the General Motors centre he himself designed every interior detail. Later, as the interior design profession grew in skill, Saarinen and others found that there were trained professionals to whom the interior design could be delegated.

A good example of this more recent collaboration between architect and interior designer is the headquarters complex for the Connecticut General Life Insurance Co. outside Hartford, completed in 1957. The architects, Skidmore, Owings & Merrill, delegated the interior design assignment to Knoll Associates' Planning Unit, whose designers were in complete sympathy with the architects' approach. At Connecticut General, and in many industrial and commercial structures since, the interior designers sat down with each executive of the client company, studied his or her needs, built models of different kinds of office spaces, and arrived at special solutions to many special problems. In some other instances, interior designers have built full-size mock-ups of offices to show each executive what sort of space he or she might expect in the new building.

In other countries, especially in certain parts of Europe, interior designers are frequently required to work within the framework of existing buildings. Sometimes the contrast of the ornate architecture of the past with the simple, light and almost transparent furniture of the 20th century enhances both. In Italy in particular interior designers have been successful in creating such harmony by contrast.

The interior designer is now an accepted, indeed essential consultant to architects throughout the world. In the United States, in the Scandinavian countries, in Japan, in Latin America—in short, wherever specialization has become a part of modern life—interior designers are found to collaborate with architects. In Germany, the birthplace of the famous Bauhaus (*q.v.*), interior design has long been an accepted discipline.

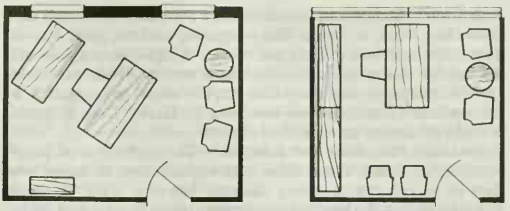
2. Design Procedures.—Interior design begins with the concept of the building. It is the architect's function to envision the basic interior space and anticipate the problems of detailed planning. The interior designer's work includes programming, space planning, relation of design to mechanical equipment, selection of materials and colour, furniture design and placement and, finally, selection of art objects and accessories. The line between architecture and interior design is impossible to define precisely.

Programming.—A program of the client's needs is of paramount importance in achieving a successful design. The client himself shares in this responsibility; he must thoroughly analyze his needs and present them to the designer, who, by applying his professional knowledge to the total problem, is then able to formulate a final program that will best serve the client's needs, functionally and aesthetically.

Space Planning.—Once the general concept of the design is developed, the next step is the planning of space. This is determined by the size and nature of the building plus the needs of the client. Because of the high cost of building, every square foot of space must count. It is important for the designer of a large building, with a multiplicity of room units, to study the basic requirements in detail. Careful arrangement of the furniture units can result in a significant saving of space. The floor plans illustrate this point.

Plan A is a typical office plan of the 1940s. Except for variation in size, it was standard for offices ranging from junior executive to company president. In such an office there was always a diagonally-placed desk, with a table set parallel behind it, a few chairs scattered around the edge of the room, and a glassed-in bookcase. The table behind the desk generally became an unsightly storage receptacle.

In Plan B, the furniture has been rearranged and the functions of the table and the bookcase are combined in the long cabinet, which provides work surface with storage space below for books, files and a dictating machine. The office in Plan B is more comfortable and efficient to work in and it appears orderly and large, yet by careful planning the dimensions have been reduced from the 12 x 15 ft. of Plan A to 12 x 12 ft., a saving of 36 sq.ft.



UTILIZATION OF OFFICE SPACE (*see* TEXT)

This sort of economical design can be applied to any type of room—in dormitories, in hospitals, in schools. The object is not to make rooms smaller simply to reduce cost but to make them the size that they reasonably should be to fulfill their function.

The importance of planning to achieve economy of space in a multiple-unit building is indisputable. Nevertheless, even in the most economically-planned building some areas should have a sense of spaciousness for visual counterpoint to a series of small rooms.

Relation of Mechanical Equipment to Interior Design.—In conjunction with space planning the designer must consider the visual appearance of such mechanical features as air conditioning, heating and lighting. These items, if selected and placed properly, can be a handsome addition to a room. If their placement is not carefully planned, however, the walls and ceilings of the room may be defaced by unsightly grilles and lighting fixtures.

Several methods of concealing air conditioning and heating units have proven successful in achieving an integrated interior. One of the simplest is a perforated acoustical ceiling which admits or exhausts air into the ducts through small holes, leaving the ceiling surfaces smooth except for lighting fixtures. Another effective system is a linear register, a long, narrow slot or parallel series of slots which run the length or width of the ceiling. Another system, particularly effective for large areas, is an open gridwork of vertical acoustical baffles, first employed in the General Motors Technical centre. This system, simple to build and maintain, provides economical distribution of ducts, registers and lighting units above the baffles and creates the over-all illusion of a ceiling.

The lighting of a building is a functional element, but it also has emotional appeal. The objective is to promote better vision in work areas and provide the right atmosphere in any kind of space, for without the proper kind of light a room loses its character. Good light is not a matter of abundance, but of the right type for the right location. A sewing room on Seventh avenue in New York may need 500 foot-candles of shadowless light; a dinner table may be charmingly lighted with candles. Fluorescent lighting is generally most serviceable and economical for utilitarian areas, whereas incandescent fixtures are more attractive and suitable for most other areas. The sources of light may be from the ceiling, walls, or even the floor.

The fields of air-conditioning and illumination are at the threshold of new developments. Such inventions as electronic temperature conversion for heating and cooling and electroluminescent room lighting promise exciting new solutions for the future.

Selection of Materials and Colour.—The character of an interior is established by the building itself, by the climate, by the occupants of the building, and by the basic design concept. The creative process is stimulated by seeking individual expression for each of these. The basic concept, once established, is a guide for the selection of colours, textures and furnishings.

Colour is an exciting tool of the designer. In nonresidential as in residential buildings, it sets the atmosphere and mood. It responds to light, natural or artificial. People react to colour emotionally, and their preferences are based on this emotional response. (*See* also *Light and Colour*, above.)

The main sources of colour are floors, ceilings and walls. The selection of wall materials is limited only by budget and suitability. Flooring, more than any other interior building material, must be selected with maximum attention to maintenance and wearability. In most commercial buildings floors are of asphalt or plastic tile,

except where budget and use allow more permanent materials such as marble, stone or glazed tiles. Lighting and acoustics also influence the selection of floor materials. A light-colored floor aids the lighting system of reflection. Hard surface floors may create acoustic problems, and they thus require some compensation by the use, elsewhere, of sound-absorbing surfaces. Deep carpeting is itself, of course, an acoustical element.

Furniture Placement and Selection.—The preference of people for familiar forms about them may explain why so many were slow to accept contemporary designs; however, with its use in many large installations, contemporary design has become an accepted form.

Production copies of furniture by English and French 18th-century designers and by early American craftsmen are not particularly suited to the requirements of large commercial buildings of the 20th century. Pieces designed to meet the aesthetic and economic demands of today are more logical choices for these buildings. Beautiful antiques may have limited use in very special areas, providing they meet the requirements of proportion and proper scale, essential to all good design. The curved lines of a Louis XV chair, for example, effectively complement the simplicity of contemporary forms; however, both rarity and economics curtail the use of antiques.

Contemporary furniture is varied in form because it employs new materials and manufacturing techniques. The molded plastic chairs of Charles Eames and the molded pedestal furniture of Eero Saarinen have beautiful flowing forms unique to the material. Harry Bertoia's sculptured wire chairs have a graceful linear volume. Many straight, simple pieces have been designed in wood and metal. One of the most beautiful chairs is the classic stainless steel-and-leather chair designed by Mies van der Rohe for the German pavilion at the Barcelona exposition in 1929.

Furniture should be selected as carefully as colours. Too many unrelated shapes in an office have the same jarring effect as too much colour. It may be advantageous to relate the dimensions of furniture to the building module. In this way sofas, desks and storage pieces can be co-ordinated with a flexible partition system to fit a wide range of room sizes, creating an order that is both visual and functional.

Placement and scale of furniture can alter the basic proportions of a space; for example, a small, low-ceilinged conference room will appear higher, and both the furniture and room will seem to be in better proportion, if the table height is lowered. Designing for large, open spaces, such as halls or entrance lobbies, presents a problem of scale. Relating the furniture to ceiling height instead of man's height would result in a disproportionate design. The Barcelona chair by Mies van der Rohe, for example, has an elegance and monumentality which make it eminently suitable for large areas.

Art Selection and Finishing Details.—The final step in finishing the interior is the selection of the right art objects, plants, and accessories, without which a room appears cold and incomplete. These must be chosen with the same consideration for scale, colour and texture that has determined all other elements of the interior.

During the Renaissance, painting, sculpture and architecture were closely allied. In the early part of the 20th century this alliance was rare; with a few exceptions the use of art was very limited. Gradually, however, the interest in art for commercial interiors increased. Painters and sculptors were being commissioned for specific building projects, and some large organizations have established art programs for their buildings, purchasing original paintings and sculpture and lithographs. The increased use of art greatly enriches contemporary interiors.

The final details are as essential to the creation of a well-integrated interior as are its basic structural elements. When all are properly interrelated in the design scheme, the result is the attainment of the designer's goal, a goal which applies to 20th-century interior design as to any great period of the past; an interior which is beautiful and serves its purpose.

INTERIOR DECORATION, HISTORY OF. This article outlines the history of interior decoration and is designed to be read in conjunction with the article FURNITURE DESIGN, arranged on similar lines, so that a picture can be obtained of interiors of all periods in most parts of the world. For practical decorative planning *see* INTERIOR DECORATION and the various articles referred to there. As the religious and monumental types of buildings are dealt with separately (*see* ARCHITECTURE [ARTICLES ON]), the present article is devoted chiefly to domestic buildings, and is divided into the following sections:

I. Introduction
II. Ancient Civilizations
  1. Egypt (*c.* 4500 B.C.–*c.* 1090 B.C.)
  2. Mesopotamia (*c.* 4000–330 B.C.)
  3. Crete, Greece and Rome (*c.* 3000 B.C.–A.D. 476)
III. The Middle Ages
  1. Early Medieval Europe
  2. Late Medieval Europe

VIII. The Modern Movement

I. INTRODUCTION

The desire to enrich the surfaces of a building usually arises as soon as the structural problems are solved. Treatment of interior surfaces, which was at first restricted to the application of colour to a plain wall surface, developed and became elaborated in the use of many different forms of pattern and material.

At its highest level, the function of interior decoration is to enhance the effect of the whole without obtruding as a separate element. As a general rule it should emphasize the architectural lines of a building although in many instances it has been used as a means of improving or correcting imperfections. At a more modest level the aim of interior decoration is to provide pleasant, comfortable and practical surroundings. On a small scale this has been achieved most successfully by overall simplicity combined with high quality of materials and craftsmanship.

Historical examples give some idea of the numerous resources employed by designers, decorators and craftsmen to excite admiration or create illusion. The overall style in any period reflects, to a great extent, the political and economic conditions. Secular building and decoration has often been the most powerful symbol of status, notably in the reign of Louis XIV of France and in

18th-century England. Fashion and the search for novelty have always played some part in directing trends of interior decoration but the expense of experiment acts as a general counterbalance.

The dominant influences, climate and availability of materials, determine the national or regional characteristics, which may be maintained through many changes of taste and style.

II. ANCIENT CIVILIZATIONS

1. Egypt (c. 4500 B.C.–c. 1090 B.C.).—In contrast with the monumental tombs and temples of stone, many of which remained intact down to the 20th century, Egyptian houses were built of perishable materials of which little has survived. Sun-dried or kiln-burnt mud bricks were used for the walls, and roofs were generally of reed or palm-leaf thatch over timber. Some smaller rooms may have been vaulted with brickwork; floors consisted of beaten earth and a thin coat of smooth mud plaster was often used as an internal wall finish.

In its simplest form the applied decoration was a plain white or coloured wash but in larger houses patterns in varying degrees of elaboration were painted on the plaster. Rush matting was hung across most internal door openings and used as screening inside the small, high windows. It is probable that decorative wall hangings and floor coverings were made of rushes or palmetto woven into a pattern, since painted representations of such hangings have survived from the 5th dynasty in the tombs of Ptahhotep and Ti at Saqqarah. In the workmen's village of Kahun, built in the 12th dynasty (*c.* 1900 B.C.) some of the more well-to-do houses contained rooms decorated with 1-ft.-high brown-painted skirting, then a 4-ft. dado (the term applied to a lower portion of wall which is decorated differently from that above it) striped vertically in red, black and white. Above this the walls were buff coloured, with brightly painted decorative panels in the more important rooms. Outer doors were of wood, fastened with bolts and latches, and ceilings were also often of painted wood. It may be assumed that the lavish tomb decoration of all periods was basically derived from the domestic interiors of their time.

Many Egyptian decorative motifs are stylized from natural forms associated with the life-giving Nile. The lotus bud and flower, the papyrus and the palm appear constantly with borders of checkered patterns or coiled ropelike spirals, giving an air of space and elegance. The palace of Ikhnaton and other large houses at Tell el Amarna (*q.v.*; *c.* 1365 B.C.) reflect a tendency toward naturalism. Ikhnaton, Nefertiti and their daughters are frequently represented, usually grouped affectionately together. Other painted panels show animals and birds with twining surrounds of vegetation. Molded coloured glazed ware was introduced to give a brilliant inlay of grapes, poppies, cornflowers and daisies, all in natural colours. The use of square ceramic tiles as a wall surfacing was uncommon but not unknown. Primary colours were the most common, a brilliant yellow being among the most frequently used, but terra cotta, gray, black and white were all added to give contrast. Even floors were delicately painted to represent gardens or pools. One of these at Amarna shows a rectangular tank with swimming fish and water fowl, bordered with lotus, and papyrus marshland with an outer band showing more birds and young cattle in the meadows beyond. Furniture ranged from the simplest benches and ceramic pots to beautifully designed chairs, small tables and beds in the homes of the rich, where innumerable vases, urns, ceramic, wood and metal utensils evince a fastidious and yet luxurious way of life.

(M. A. M.; E. C. D.)

2. Mesopotamia (c. 4000–330 B.C.).—The mud-brick houses of the Sumerian and Old Babylonian periods in the Tigris-Euphrates valley resembled their modern counterparts in their rectangular outline and the grouping of rooms about a central court, which was either roofed or open. In the majority of houses decoration probably was confined to a wide black or dark-coloured skirting, painted in diluted pitch, with a band of some lighter colour above. Door frames were sometimes painted red, probably as a protection against evil influences, and where doors were used they may have been of palm wood. The poorer houses were simply whitewashed inside and out.

In the most elaborate Assyrian palaces the main decorative features were panels of alabaster and limestone carved in relief, the principal subjects being hunting, ceremonial and war, as in the palace of the warrior Sargon II (*see* SARGON) at Khorsabad (706 B.C.). Panels and friezes of ceramic tiles in vivid colours decorated the walls inside and out and it is evident that this brilliance of colour was a feature of much Assyrian and Babylonian decoration. Carved stone slabs were used as flooring with typical Mesopotamian rosette and palmette borders. Occasionally, Egyptian lotus motifs also appear.

Vigorous and warlike figures characterize both Assyrian and Babylonian work and the standard of execution was extremely high. Naturalistic detail was often engraved on the surface of the figures and animals which themselves were in relief. After the Persian conquest (539–330 B.C.) this vigour declined. The palace built by Darius and Xerxes at Persepolis shows a lighter use of animal figures. Glazed and enameled tiles were used on the walls, while timber roof beams and ceilings also received vivid painted colour.

(E. C. D.)

3. Crete, Greece and Rome (c. 3000 B.C.–A.D. 476).—The most important buildings of the pre-Hellenic Minoan and Mycenaean periods were the citadel complexes, housing the entire court of the ruler. The palace of King Minos at Knossos in Crete (*c.* 1500 B.C.) gives evidence of a small but sophisticated society with a taste for luxury and entertainment and a corresponding skill in applied decoration. The palace was constructed from large blocks of stone, with stone and painted timber columns supporting the lintels or roofs; much of the paving was also of stone. Extensive frescoes and some panels in painted relief decorated the walls of living rooms and ceremonial rooms, which were grouped asymmetrically round a series of courtyards. Many aspects of Cretan life were depicted, the recurring theme being the acrobatic bullfighting on which a religious cult was probably centred. The figures are wasp-waisted and fashionable; male figures are usually painted in red, female figures in yellow, and both wear gold and silver ornaments. Even the backgrounds to friezes and panels, which depicted many-coloured painted birds, animals and flowers, were given an effect of movement, being divided up into light and dark areas. Plain dadoes and borders provided an effective foil and gave articulation to the interiors. A fragmentary imitation of column construction can be seen painted on the walls of the "stepped pavilion," having yellow sham pilasters capped with blue, dadoed in red and surmounted by an imitation architrave in yellow. A narrow frieze of birds above is divided from the ceiling by an even narrower cornice banded in yellow, black and white.

As seafarers, the Cretans could import a rich variety of materials for building and decorative purposes; a wealth of ideas, also, can be seen in the fine pottery, carved ivories, beaten gold, silver and bronze with which their palaces were ornamented. (*See* also CRETE.)

The flowering of Hellenic culture, culminating in Athens in the 5th century B.C., was manifested more in the exterior perfection than the interior treatment of its architecture. In an age of temples and public buildings, dwellings were relatively unimportant. In most cases the Greek house looked inward to a courtyard or to a large, high central room and was built of unbaked brick, with a tiled roof; very little is known of the details of its decoration.

In the Hellenistic period (323–31 B.C.), domestic comfort and decoration were considered once more. Mosaic floors were an important decorative device, originally being made of pebbles as at Olynthus, but later developing into the black and white or coloured mosaics which were widely used throughout the Roman empire (*see* MOSAIC). A central finely designed panel with realistic motifs and a wide, more coarsely executed border of scroll or key patterns acted as a focus for the arrangement of furniture, which was still limited in quantity.

Greco-Roman decoration has been well preserved at Pompeii, Italy, where painted wall decoration began about 150 B.C. By about 80 B.C. plastered walls were being made to look like masonry, with a plinth or dado and several courses of imitation stonework in molded plaster, surmounted by two molded cornices separated

by a flat frieze. Such decoration was combined with the true architectural features—doors, architraves and pilasters. The panels are painted variously in yellow, black, magenta and red with some imitation marbling indicating an earlier custom of applying marble veneers. Rich colour was also supplied by superbly executed mosaic floors, elegant couches with coloured cushions, bronze tripods and lamps, such as those seen in the frescoes at the House of the Faun, Pompeii.

Roman wall painting depicted columns, niches and open windows with elaborate imaginary views and figures beyond. Broken entablatures and painted ruins, as seen in the House of Livia, Rome, were the precursors of the 18th- and 19th-century romantic taste in western Europe.

In the 3rd and 4th centuries A.D., the variety of coloured marbles, imported from Egypt, Greece and various new quarries in Italy, provided fresh material for veneering walls and laying patterned marble floors of *opus sectile*, as at Ostia (*q.v.*). Painted architectural features were still used to frame the wall panels, and formed an integral part of the interior design. Brilliant colours were applied in tempera, oil or encaustic (a preparation of heated wax mixed with pigments which provided particularly vivid and durable colours). Fine stucco was sometimes molded in relief, and modeled terra-cotta plaques and friezes showing mythical and pastoral scenes were let into the walls. Ceilings, which were often vaulted, were frequently coffered (decorated with sunken panels) or painted to resemble coffering. Painted or modeled medallions were introduced, and glass mosaics were applied occasionally to vaults, apses or the soffits (undersurfaces) of arches—for example at the Baths of the Seven Sages, Ostia.

Most of the present knowledge of furnishings and hangings in Rome and its provinces comes from surviving paintings and reliefs. Mattresses, cushions and pillows had colourful woolen or linen coverings woven in intricate patterns, and were sometimes tasselled or valanced (bordered with cloth). The courtship of Venus and Mars in the house of Marcus Lucretius Fronto, at Pompeii, shows a couch draped in dark green, scarlet and purple, striped and banded in yellow and other colours, and a stool with a red, gold and blue covering and a golden fringe. Fur rugs, cloth of gold and Chinese silk were used occasionally and fragments of such materials have been found in tombs at Palmyra, Syria. From Doura-Europus, also in Syria, a piece of material survives with shaded pink and red roses outlined in tan on a green ground. Elaborate furnishings of this kind are mentioned by Horace, Propertius, Cicero and other writers. Statues and statuettes of bronze or marble, vases or dishes of painted and glazed pottery, silver, bronze and coloured glass adorned the homes of the rich. Lamps of varied shapes made in pottery or bronze and braziers and water heaters of bronze also were found at Pompeii. (JN. L.; E. C. D.)

III. THE MIDDLE AGES

1. Early Medieval Europe.—In the 4th and 5th centuries, with the weakening and ultimate fall of Roman order and administration in a large part of western Europe, secure and civilized life came to an end and its refinements vanished, some for five, others for ten centuries. Indeed, certain amenities, such as adequate domestic heating, did not begin to emerge again until the 20th century.

Constant war was waged against invaders from Asia and from northern Europe and material possessions dwindled to a minimum: a man did not own for long anything he could not defend and had little use or opportunity for interior decoration. If he possessed more than one house, his furniture and possessions would go with him from place to place. The arts were monopolized by the church which grew rapidly in the early middle ages and later dominated all aspects of the Gothic world.

Late into the medieval period the larger houses were designed according to military rather than aesthetic principles. The main room was a spacious hall with timber or stone walls (sometimes plastered), an open-beamed roof, narrow slit windows as yet unglazed, and a floor of stone slabs, tiles or beaten earth. In the earlier houses the fire burned in the centre of the floor and the smoke either drifted through a central hole in the roof or dispersed among the rafters, but wall fireplaces soon replaced this unsatisfactory system. Furniture was probably limited to plain stools, benches and trestle tables, made of local timber, and some heavy chests in which clothing, hangings and other personal possessions were stored. The feudal lord and his lady sat on more elaborate chairs on the dais (raised platform), and a coloured hanging of plain fabric sometimes decorated the wall behind them. Wall hangings and tapestries became more common in Norman times, when stone carving on doorways, fireplace, window openings, column capitals and arcading superimposed on the inside walls was also introduced and can still be seen in the Norman castles of Rochester, Kent, and Chepstow, Monmouthshire, in England. The whole community often lived and slept in the one hall, but as time went on two main rooms, the hall and the chamber, were provided. At first rooms were divided by woolen hangings, hung from iron rods or from the rafters; solars (withdrawing rooms) and cabinets or bowers for women's work and recreation developed in this way. The houses of the poor were simple timber-framed shelters with bare earth floors and undecorated walls lined with wattle and daub. Such conditions, with variations according to local circumstances, were generally prevalent in western Europe down to the end of the 12th century.

2. Late Medieval Europe.—The spread of eastern influence resulted in great advances and in some cases, for example Spain and Sicily, it had already begun to take effect in the 12th century. The curious hall of King Roger II (12th century) in the Norman Palazzo Reale at Palermo, Sicily, shows Byzantine derivation in its marble-faced walls and mosaic-encrusted ceiling.

During the 12th and 13th centuries many of the more important landowners and military leaders in France and neighbouring countries took part in the crusades and learned something of luxurious living in the near east. As a more secure way of life was becoming possible at home, they began to improve their own living conditions. Fortification diminished and the castle slowly evolved into the manor house. Household equipment became more elaborate and important, no doubt partly because the women had played a greater part in household management since the absence of their menfolk on the crusades.

Curtains of finer texture began to replace wooden window shutters or heavy homespun hangings. Tapestries relieved the bareness of the walls and gave additional warmth to rooms. Other textiles and tapestries were draped over chairs and tables, and brightly coloured woven or embroidered cushions were used. The fine wood ceilings of the large rooms were sometimes coffered and often painted in bright colours, particularly in France. The disappearance of much of this colour with the passage of time lends a false austerity to surviving medieval interiors.

A greater number of rooms, serving special needs and giving increased privacy, came into use although the house was still not planned as a whole. The kitchen, buttery and pantry were placed at the lower end of the hall beyond a carved timber or stone screen which, in larger houses, supported a minstrels' gallery. At the opposite end, the chamber, or withdrawing room, may have had a solar above it, used as a bedroom or as a special apartment for the ladies. A guest room was occasionally provided. In the 13th and 14th centuries, the wardrobe was a room with presses for storing curtains, hangings, bed and table linen, as well as the clothing and materials needed by the members of the household. Here sewing and tailoring were carried on and the room became a combined workroom and store, furnished with heavy, plain tables and chairs.

In the kitchen, rotating spits and adjustable hooks for suspending cooking pots were fixed into a vast hooded or recessed wall fireplace. Plain but pleasing utensils of wood, copper and iron were kept on hooks on the walls and stools and enormously solid tables stood on the stone or tiled floor, which was strewn with sawdust or rushes.

In the hall the rushes were mixed with fragrant herbs and helped to absorb some of the dirt, smells and grease. By the 15th century, plaited rush mats were common. The introduction of linen tablecloths resulted in a great improvement of manners and cleanliness at meals. Gold and silver plate was displayed in the wealthier

houses and pewter dishes and plates were used. The rooms were lit by tallow or beeswax candles set in wood or metal candlesticks, or lamps formed of a floating wick in a bowl of oil, as well as by torches, standing candelabra and wall sconces.

Ornaments and various luxuries, which had become more common during the time of the crusades, proliferated in subsequent centuries as commerce with the near east increased. Household plate, of gold or silver, was frequently displayed on dressers or cupboards as decoration and to impress visitors; it was not unknown for these to be roped off to prevent pilfering. Indoor arrangements for washing and bathing were considered a luxury. A long trough with a row of taps in the courtyard served most of the household; sometimes there was a tank or cistern with running water. A flat-sided metal bowl was fixed to the wall of a living room, with a swinging ewer or a small cistern with a tap over it and a towel on a hinged rod. Small convex mirrors were hung on the walls as early as the 15th century (one appears in the famous portrait of Giovanni Arnolfini and his wife by Jan van Eyck in the National gallery, London), but only hand mirrors, usually of polished metal, were in general use.

One of the most complete early domestic dwellings remaining in England is Stokesay castle in Shropshire, a fortified manor dating in part from the 13th century. The large hall has a high open-beamed roof, unglazed windows with wide stone seats and a floor of beaten earth. An outside flight of stone steps leads to the solar where there is a built-in fireplace. The house has other separate rooms and exemplifies the development of privacy in English domestic arrangements. Henry III (1216–1272) of England was not only an enthusiastic builder, for example at Westminster abbey, but also a connoisseur of house decoration. The liberate rolls of his reign preserve all the orders he gave for the adornment of his castles and manor houses. Larger windows, and especially rose windows, were built in the halls, their painted glass adding the rich colour which pleased the king and which he achieved at other times by having "histories" painted on his walls, as in the Great chamber at Westminster palace. The frescoes generally depicted historical, biblical and classical scenes and were often executed above wainscoting with painted and decorated boarding. His queen, Eleanor, commissioned an allegorical figure of winter to be painted over the fireplace in her room at Westminster, and springlike flowers on the walls of her whitewashed room in the Tower of London. Roofs were also carved and ceilings painted. Such rich treatment was rare throughout the rest of the country where walls remained bare and hangings were the usual means of decoration used by the wealthier classes.

An illustration from the *Très Riches Heures du duc de Berry*, the celebrated manuscript at Chantilly, France, gives a striking picture of seignorial life in the first half of the 15th century. It represents King René I of Naples seated at a table; behind him is a circular screen of rushes which protects him from the heat of the large hooded fireplace, the wall is covered with tapestry hung on hooks, a white cloth covers the table, and there is rush matting on the floor.

In the Alpine lands, such as Switzerland, the Tirol and south Germany, the use of fir, pine and other soft local woods largely determined the form and ornamentation of interiors. Floors, walls and ceilings were made entirely of wood, as they often continue to be. A bedroom from the Landesfürstliche Burg at Merano, Bolzano province, Italy, is a remarkably well-preserved example of the interior of a well-to-do house in the latter half of the 15th century. Swiss furnished interiors are exhibited at the Historisches Museum in Basel, though only in one case dating back to the medieval period, and there are others in the Historisches Museum, Bern, and Schweizerisches Landesmuseum, Zürich, which cover the period from the 15th to the 17th centuries. Floors are of wood; walls and ceilings are paneled and molded. The moldings are bold, but any carving is usually in slight relief because of the nature of the wood; sometimes there are simple, geometrical inlays of harder and more ornamental woods.

The Castello d'Issogne, in the Valle d'Aosta in northern Italy, exemplifies a medieval domestic interior adapted to the mild climate south of the Alps, where the Gothic style never became so firmly rooted as in northern Europe. The castle was built about 1490 and, though medieval in structure and appearance, is not a stronghold but a summer resort. It is built in a square with a tower at each corner. A kind of vaulted portico supported by pillars opens on the inner courtyard; this was used as a hall, and is furnished with wooden linen-fold paneling and a fixed bench running along the wall. The lunettes above the paneling are filled with frescoes illustrating scenes of daily life—the shops of a provision merchant, an apothecary, a tailor and a draper, and an outdoor market and soldiers in a guardroom. There are also a dining room, an armoury, a kitchen, a servants' hall and a chapel. The coffered ceilings are carved and painted.

Tapestries were hung curtainwise from wood quartering set with tenterhooks; at Tattershall castle, Lincolnshire, Eng., this quartering has been restored, and a great chimney piece carved with heraldic designs and dating from about 1436 is also noteworthy. Flanders tapestries, known by the generic name of arras, were favourite hangings and, being solidly woven, they resisted the wear and tear caused by being moved frequently from house to house. In the 15th century it was not yet customary to have the walls lined with paneling (although wood was used for structural purposes such as hall screens and room partitions) and, except where covered by hangings, the brick structure of the walls was visible. An illustration from an illuminated manuscript (*c.* 1475) made in Flanders for Edward IV shows Richard II sitting under a rich cloth canopy and behind him the brick walls of the hall.

In the 15th century communications improved and there was a corresponding increase in the use of imported ideas and materials such as silks, velvets and cloth of gold; although oriental pile carpets were rare in Europe before the 17th century, they were probably introduced into England by Eleanor of Castile, wife of Edward I. With the advent of the Tudor period English interiors began to take on a more familiar appearance. Large windows followed a similar trend in church architecture and the use of carved paneling and other interior woodwork was extended. Even so, they could not rival the more sophisticated and colourful French interiors or the comfortable solidity of town houses in the Netherlands. (J. E. Le.; E. C. D.)

3. Muslim Countries.—The Arab conquest in the 7th century A.D. and, in the 8th century, Muslim expansion into India and Spain had profound influence on the decorative arts throughout the known world, especially as most of the long-distance trading routes passed through Arab lands. The skills of the conquerors fused with the traditional skills of their subject peoples and as Islam forbade the portrayal of human or animal form, whether for religious or artistic purposes, and encouraged the incorporation of Koranic texts into design, religion played a considerable and direct part in the development of design. As with nearly every other society, the finest and most lasting buildings were of a religious nature, and unfortunately few domestic dwellings have survived.

Architectural quality and form were subordinated to intricate and richly coloured surface decoration. Perhaps the finest results were achieved in Persia, where a high level of technical ability already existed in combination with great lyrical sensitivity. Here the principal decorative features were the ceramic tiles and tile mosaics which encrusted floors, walls, roofs and domes both inside and out. The mosques of Isfahan, Meshed and Tabriz, ranging in date from the 13th to the early 17th centuries, demonstrate a completely satisfactory use of colour in architecture. Lustred tiles with a combination of floral and geometric design date from the 10th and 11th centuries and naturalistic flowers frequently give a gardenlike effect to the tile decoration. Iris, rose, carnation, tulip, pomegranate, pine and date are depicted, always with delicately interlacing stems, and contained within plain or patterned borders. Blues of all shades, from turquoise to a deep ultramarine, are characteristic.

Patterns for tilework and patterns for the Persian carpets are frequently interchangeable. Somehow, for reasons not yet fully understood, carpet designers soon managed to circumvent the ban on the use of animal forms; lions, deer, leopards, ornamental birds and occasionally even mounted huntsmen were depicted,

the figures always judiciously placed to give the maximum decorative effect. Artistic achievement reached its peak under Shah Abbas (A.D. 1587–1629), but well before this time Persian carpets, silks and pottery were known and valued in western Europe, as they still are in the 20th century.

In Cairo and Sicily one of the results of Muslim domination was the introduction of a high degree of ornamentation on wall surfaces, once again principally by means of vividly coloured ceramic tiles. The patterns are more solid than those of Persia filling up the areas between the containing arabesques and with less open backgrounds. Moorish design in Spain shows even more complex interlacing geometrical framework which is filled in with formalized leaves, flowers or calligraphic inscriptions in Kufic and, later, cursive script. Ceilings and the upper parts of walls were modeled in flat relief with coloured and gilded arabesques, while the lower wall areas were tiled. The decoration was partly hand chiseled and partly molded. Such decoration may be seen in the Alhambra, built at Granada in the 13th and 14th centuries, a pleasure palace whose arcaded courts and halls are embellished with stuccoed decoration in honeycombed ceilings, stalactite vaults and capitals, tiers of horseshoe-shaped or stalactite-fringed arches, and pierced or latticed windows.

In the mosques of Turkey walls were veneered with marble and ceramic tiling was introduced only in small areas. Colours, too, are less exuberant in the large mosques, where a sense of space rather than of overwhelming decoration is pre-eminent. Domestic buildings were largely of wood, looking inward to secluded courtyards and gardens, but with elaborately latticed windows projecting at upper-floor level over the street. As in most other Muslim countries, the wealthy furnished their houses with velvet and silk hangings, couches and innumerable cushions.

Islamic influence in India appears at its finest in mosques and tombs of the Mogul period (1555–1707); coloured marbles and sandstone produce a more monumental architecture typified by the Taj Mahal at Agra (*see* INDIAN ARCHITECTURE).

IV. THE ORIENT

1. China.—Architecture has never been the principal medium for the expression of the Chinese artistic impulse; conservatism, perhaps rooted in ancestor worship, has been paramount and stylistic innovation practically unknown. The basic structure of the Chinese house has remained almost unchanged at least from the Shang dynasty (*c.* 1300 B.C.). In all types of buildings the roof is the most important feature and by the T'ang dynasty (A.D. 618–906) the characteristic upturned eaves and heavy glazed and coloured tile covering had developed. The roof is chiefly supported by timber posts on stone or bronze bases, and the walls of the building serve merely as screens in brick or timber. Floors are often of beaten earth packed tightly into a timber surround. Usually a family house was composed of a series of buildings or pavilions enclosing a garden courtyard and surrounded by a wall. The courtyard played an immensely important part owing to the ever-present ideal that man should live in harmony with nature: a small pool with a lotus plant, a tree and large rocks symbolized the whole natural landscape and it was on these features that most care was lavished.

The supporting pillars and brackets of important buildings were carved and painted, many of the designs being similar to those made familiar by Chinese pottery and porcelain. The yellow dragon symbolizes the power of the spirit, the tiger the forces of animal life. Windows were latticed with strips of wood in varying patterns over which translucent white paper was stretched. In addition to the lattice-work patterns, the windows themselves took on great variety of outline, for instance that of a diamond, fan, leaf or flower. Doorways, too, were fancifully shaped in the form of the moon, lotus petal, pear or vase, as structural support was not required from the light panel-type walls. Some walls may have been removable altogether as they were subsequently in the Japanese house; others were of painted wood, hung with tapestries, or paintings on silk and other materials.

Furniture, probably dating back to 500 B.C., was made with patient craftsmanship. Low stools and tables were early in use, and chairs, dressing tables, altar tables and canopied beds were common by the early Han dynasty (206 B.C.–A.D. 9). Designs and materials underwent very little change in the intervening years. Rosewood has always been widely employed and in the palaces elaborate pieces were encrusted with gold and silver, jade, ivory and mother-of-pearl. A description of a Ming (1368–1644) home of the leisured class mentions ceilings with *cloisons* (compartments) in yellow reed work, papered walls and pillars, black polished flagstones and silk hangings. Richly coloured rugs, chair covers and cushions contrasted with dark furniture, which was arranged according to strict ideas of asymmetrical balance.

Scrolls of painting or calligraphy were displayed, being changed from time to time to give freshness to the decorative scheme and also to emphasize their quality. Similarly a vase with a single branch of peach blossom or other flowers would be set out with care. Cabinets and storage chests were of great importance and were often made of camphor wood. An important feature in the houses of north China was the *k'ang* or heated brick platform, on which the family slept or sat in the cold northern winter.

(E. C. D.)

2. Japan.—Interior decoration in Japan was much influenced by Chinese ideas especially between the 8th and 12th centuries, but it developed on lighter, more austere and elegant lines. As in China it has altered little since medieval days. The most important differences in modern design are that sliding doors have replaced single-leaf screens or curtains and the matting has been extended to cover the whole of the wooden floor.

By the 9th century doors were pivoted in the Chinese manner, and instead of the sliding *shoji*, windows were made of wooden latticing that pushed outward, such as may be seen still in shrines and temples. There was a curtained dais for the most important person and separate mats on the wooden floor for others. Then, as now, there was a connecting corridor outside the rooms. The *Seiryoden*, or ordinary residence of the sovereign in the Kyoto palace, belonged to this period and was reconstructed in the 19th century on the model of the original. A present-day family could live quite comfortably in its simple suite of rooms with walls and standing screens decorated with pictures in the Chinese classic manner.

Late in the 15th century the interior began to assume its present form as a result of a slow blending of the older court style with the more austere type of house favoured by the military caste, which was much influenced by Zen Buddhist architecture. Toward the end of the 16th century came the rise of the tea masters under the autocrats Oda Nobunaga (*q.v.*) and Toyotomi Hideyoshi. These connoisseurs of the "Way of Tea," which involves the construction of the tearoom and its garden and correct deportment in them, established hereditary families and schools who remained the aesthetic advisers on most aspects of domestic architecture, interior decoration and garden planning. They aimed to achieve beauty with frugality, asymmetry and economy of movement, and much of the simple grace of Japanese interiors is due to them.

In a modern Japanese house decoration is almost entirely constructional and the residences of all classes are equally neat and free from vulgarity. Their harmony and delicacy derive from an endless variation of detail in a setting that is completely standardized. The ordinary rooms are multiples of the floor-mat unit of 6 ft. by 3 ft., the sliding doors 5 ft. 8 in. high by 3 ft. wide, the supporting pillars 4–5 in. square, set at 6 ft. intervals, and the ceiling boards 1 ft. to 1½ ft. wide. All woodwork is unpainted and rarely lacquered but there is a great variety in the *fusuma* or sliding doors which divide the rooms and which are covered with paper of many patterns or decorated with paintings or calligraphy. Thus the whole side of a room may present a landscape either in black and white or in colours, often on a silver or gold background. A change of these fusuma will alter completely the appearance of a room and their removal will convert two or more rooms into one. All rooms can be used as bedrooms, since the bedding is stored in spacious cupboards. The reception rooms provide more scope for decoration than the others, for one end of the room is occupied by a *tokonoma*, an alcove with a canopy above it supported by a pillar of fine or uncommon wood, in which

is hung the picture or set of pictures which, with the flower arrangement that usually accompanies it, is the only ornament. Both are changed frequently according to the season or mood. Next to it there is often a built-in writing table. Beside it is usually a *chigai-dana*, an asymmetric arrangement of cupboards and shelves somewhat like a sideboard. Between the top of the fusuma and the ceiling is often a *ramma*, or openwork frieze carved with patterns or landscapes in wood or bamboo. A framed tablet with a poem or painting on it sometimes may be placed there. Other walls are of plain plaster in subdued shades, mostly of gray or brown. The ceilings are usually of thin boards, slightly overlapping, upheld by bars about an inch square, the whole suspended from the roof or floor beams. In large apartments as in shrines and temples the coved and coffered "Chinese ceiling" with lacquered woodwork and pictures and patterns in the coffers is sometimes found. Fancy varieties made of bamboo and reeds and plaited wood are not uncommon. The furniture is sparse, perhaps consisting of a cabinet of blackwood or lacquer, a low writing table or a screen, either twofold or sixfold (the latter generally in pairs), decorated with landscapes on a gold or silver background and mounted in brocade. A single-leaf screen sometimes stands in the entrance hall. Among the well-to-do other valuables such as scroll pictures, braziers, pottery, spare fusuma, books and curios are kept in a detached fireproof storehouse and produced only occasionally to ensure a constant variety in the rooms. It is a principle that rooms that are only occasionally occupied may be more showy and fanciful than ordinary living rooms, and these are most often met with in hotels and restaurants and other places of entertainment. Just as much care is taken with the interiors of the bathroom and privy as with the other rooms, and the doors and windows and walls of these are usually of excellent workmanship. Those in famous restaurants are often wonderfully decorative. Bamboo has many uses in the Japanese house as pillars and window bars and ceiling material, and when split and flattened may take the place of boards. Some idea of the variety of the fitments may be obtained from the series of volumes of *Illustrations of Architectural Details* by Kenchiku Shashin Ruiju (Tokyo, 1916) that give 150 different examples of tokonoma and *chigai-dana* arrangements, 100 of *ramma*, 100 of sliding doors, about 20 of ceilings and 50 of windows. These latter are of many shapes, round, square, bell-shaped, jar-shaped, gourd-shaped, diamond- and fan-shaped and purely asymmetric, and make centres of interest in a blank wall.

(A. L. Sr.)

3. India.—Words of Indian origin such as calico, chintz, palampore indicate the importance of Indian textiles in the history of western interior decoration. Yet the Indians themselves have never been very conscious of this role, their own domestic interiors being of the utmost simplicity, with hardly more than a carpet or prayer mat to offset stone floors and plain white walls. The impermanence of the materials used for the majority of dwellings may have been a contributory factor. However, in more palatial buildings and commonly in both Hindu and Buddhist temples, walls were painted, a practice which, according to literary references, may go back to the Maurya period (323–185 B.C.). Paintings which survive, for instance in cave temples of the Gupta period (A.D. 320–600), usually depict groups of active mythical or human figures and are characterized by their sinuous lines. A late example occurs in the unfinished early 17th-century murals of the Mattancherri palace, Cochin, Madras. Inlay of semiprecious stones, carved and bracketed pillars and capitals, and openwork marble panels also adorned the palaces of local rulers.

In the 17th century, painted calico hangings and bedspreads were exported to Europe in such great quantities that the competition with home industries led to agitation against imported cloth. In 1686 France introduced restrictive legislation and England followed with the acts of 1700 and 1720. In both countries the law was evaded and throughout the 18th century Indian fabrics found their way into every fashionable English household. Yet the influence of Indian design is less revolutionary than has been generally supposed for the patterns employed were mostly of western origin. The East India company (founded 1600) in London sent sample patterns to their agents in India with instructions that the calico printers and embroiderers should produce designs "after the same manner." The samples were probably sent in a form similar to the contemporary pattern books for domestic embroideries—black and white drawings in quarto, or smaller. In making freehand enlargements, the Indian draftsman would have been compelled to invent details of the unfamiliar vegetation and animal life, which perhaps explains why common European motifs are very distorted: the oak leaf, for example, is rendered with exaggerated indentations and the strawberry fruit with unduly large seeds. The resulting designs are hardly recognizable as European and it was their exotic effect which gave them such a wide appeal in Europe.

Toward the end of the 18th century, the traditional Indian methods of calico printing by resist and mordant processes gradually gave way to the cheaper block-printing technique. This was accompanied by degeneration of design and execution, and in the 19th century Indian textiles were but a poor shadow of their earlier counterparts. (*See* also Textiles: *Indian Textiles.*)

Fine collections of the 17th- and 18th-century fabrics are preserved in the Victoria and Albert museum, London, and the Royal Ontario Museum of Archaeology, Toronto. (X.; E. C. D.)

V. RENAISSANCE TO THE END OF THE 18TH CENTURY

1. Italy.—The ferment of new ideas which produced the Renaissance showed itself first in Florence in the later years of the 14th century. Fresh interest in the ancient classical tradition, never entirely lost in Italy, provided inspiration for design and ornament. Liberal patronage of the arts was made possible by the wealth which had accumulated in the powerful trading cities of northern Italy, and was informed by the new humanist approach to the world.

Churches, palaces, private chapels and houses were lavishly built and decorated by architects, artists and craftsmen of great inventiveness and ability. The classical orders (columns with base, shaft, capital and entablature) were borrowed and adapted to dress the new architectural style. Architects became highly skilled in the treatment of space, and decoration often played a major part in defining and enriching their vigorous spatial effects. Classical architectural forms were used in plasterwork, inlaid woodwork and painted decoration as well as for staircases, doors, windows and fireplaces which formed increasingly important and elaborate features of interior design. Decorative details inspired by the antique were also used, executed in a wide variety of techniques; garlands, caryatids, lion masks and grotesques, reclining *amorini* (cupids), cornucopia (horns overflowing with flowers or fruit), arabesques (entwining scroll and plant motifs) and trophies of arms are among the most familiar. Floors of coloured and patterned marble paving are frequently integrated with the overall decorative scheme.

Modeled stucco, sgraffiti arabesques and fine wall painting may be seen at their best in the loggia of the Vatican, Rome, in the work of Raphael, Giovanni da Udine and others (*c.* 1515); the Villa Farnesina, Rome (1506), by Baldassare Tommaso Peruzzi and Raphael; the Villa Madama, Rome (1516), by Giovanni da Udine and Giulio Romano; and the Palazzo del Té, Mantua (1525–35), also by Romano.

In Venice the transition from Gothic to Renaissance building came less abruptly, as demonstrated in the Doge's palace where a Gothic exterior is found in combination with a late 15th-century façade on the east of the courtyard and a series of High Renaissance council chambers, famous for wall paintings by Veronese and Tintoretto. Wood paneling with flat pilasters and a molded frieze forms the lower part of the interior wall decoration, with the fine series of historical and allegorical paintings above, divided into panels between painted and gilded moldings and pilasters. The ceilings of a later date are particularly richly painted, their heavily scrolled carved and gilt cornices and framing introducing a touch of baroque. Windows developed with twin semicircular-headed frames surmounted by a lunette fitted into a third, larger round-arched opening and are a typically Venetian feature of the waterside palaces. In these, as in all the great Italian houses of

the time, the works not only of the finest painters of the time, but of the sculptors, goldsmiths and silversmiths, wood carvers, bronze and iron workers were used to embellish the principal rooms. Silks, embroideries and cut velvets were used as hangings and upholstery, together with elaborately cut and framed looking glasses and carved gilt pendant chandeliers as in the Palazzo Corner Spinelli, Venice (1480). Costly carpets were imported and much fine linen was in use. *Trompe l'oeil* effects of perspective were achieved in the painting of walls and ceilings and also with intarsia decorated paneling such as the Palazzo Ducale, Urbino (completed about 1500), where a startling effect is created as of open cupboards full of books.

In Rome toward the end of the 16th century, the rich, tumultuous work of Michelangelo was followed by a style known as the baroque (*q.v.*). Its deliberate exaggeration of forms displaced the strict logic and precision of the High Renaissance and aimed to convey freedom of movement and to involve the spectator in the drama of the design. Basic materials and techniques were unaltered, but all restraint in their use vanished in bold theatrical effects and sensual luxuriance of modeling. Walls became curved, pediments were broken, columns and pilasters twisted until the buildings seem to come alive with movement. Giovanni Lorenzo Bernini (1598–1680) was one of the most prolific masters of the style and used rockwork, figures and draperies in exuberant combination with columns, paneling and vaulting. Marble or stucco was made to imitate brocaded hangings as in the Sala Ducale, Vatican, where an effect of space from limited means is created. The variety of colour in baroque interiors contrasts with the more sober colourings of the earlier Renaissance decoration.

From Italy these styles spread across Europe where they were absorbed in varying degrees and tempered by the national or local taste and genius. Many Italian designers and craftsmen traveled and worked abroad in France, England, Austria and Spain. In this way the impetus of the Renaissance carried across two centuries, finally dwindling in these countries with the Neoclassicism of the later 18th century. (E. C. D.)

2. France.—From the middle of the 15th century ideas from Italy began to change the face of French buildings; this change came gradually, first in the applied decorative detail superimposed on basically Gothic designs, then extending to a symmetry and regularity of the whole. One of the basic differences between the Renaissance in France and in Italy is that in the latter the revolution in style from the start involved the whole conception of design. The centralization of power and the brilliance of court life was consolidated under Francis I (1515–47) and had already resulted in patronage of artists and craftsmen from Italy. Since the need for churches had been fulfilled in the great age of Gothic building, the king and his court rivaled one another's magnificence in building new châteaux in the early Renaissance style. Climate dictated the characteristic steep roofs, tall chimneys and large windows. Stone and timber were readily available, with masons and carpenters skilled in their use.

Among the earliest attempts in the new manner are the additions made by Francis I to the château at Blois. The spiral staircase, with its own open stonework tower, may have been designed by Leonardo da Vinci, who died nearby at Amboise in 1519. Even at this early stage, the decoration of the staircase ceiling with carved bosses featuring the monogram and heraldic device of the king shows a typical French contribution to Renaissance decoration. Such shields and monograms formed an important element in many decorative features, being used in wall and ceiling panel design or on the large carved stone chimney pieces. The fine galleries of Francis I and Henry II (1547–59) in the royal palace at Fontainebleau illustrate the increasing elaboration of applied decoration and colour. The flat ceilings are of wood, coffered, coloured and gilded in a variety of geometrical forms outlined with fine moldings. Molded panels enclose paintings on the upper section of the walls, and molded or carved wood paneling the lower parts, as in Italy. Floors are of hardwood strips, sometimes repeating the pattern of the coffered ceiling above. Benches supported on consoles are designed as part of the overall scheme of wall paneling. Italian artists had been employed at Fontainebleau and elsewhere, influencing the contemporary French architects toward a more Italian conception. Rosso Fiorentino and Francesco Primaticcio decorated the Galerie de François I while the hexagonal coffered ceiling in the Galerie de Henri II was designed by the Frenchman Philibert de l'Orme, who also designed the 180-ft.-long bridge at the Château de Chenonceaux for Catherine de Médicis. The architects Sebastiano Serlio and Giacomo da Vignola, together with the goldsmith Benvenuto Cellini, all worked for a time in France and much of the decorative work in the châteaux of the Loire valley was executed by Italian craftsmen.

In the early 17th century and during the long reign of Louis XIV (1643–1715) formality and magnificence became paramount in the life of the court. Suites of large rooms elaborately decorated provided a background for "*Le Roi Soleil*" and his courtiers, and consisted of a vestibule, antechamber, dining room, salon, state bedroom, study and gallery. Staircases were stately and spacious, providing a fitting approach to the main rooms. Decorative schemes incorporated the fittings, hangings and furniture with that of the room itself.

By the second half of the century, French influence had become so dominant that even Louis XIV's most violent enemies imitated the decoration of his palace at Versailles. In 1663 Louis and his minister Jean Baptiste Colbert appointed Charles le Brun (*q.v.*), *le premier peintre du Roi*, as director of the Gobelins factory which had been bought by the king and was newly styled the Manufacture Royale des Meubles de la Couronne. The chief aim of this organization was the production of furniture and all types of decorative furnishings for the royal palaces but it also helped to raise the standard of design and execution in France as a whole. Le Brun himself prepared designs for diverse objects, from the painted ceilings of the Galerie des Glaces at Versailles to the metal furniture for a door lock. (It should be noted that at the Gobelins, as elsewhere in France, furniture was designed by the artist or architect with no practical experience of manufacture, whereas in the great age of furniture making in England, most designs were made and executed by the cabinetmaker himself, with an intimate knowledge of his material.)

Though the baroque trend is well established in the Versailles interiors, generally speaking it was regulated in France by an underlying restraint which seldom permitted decoration or movement to dominate entirely. Besides the Galerie des Glaces at Versailles, the Galerie d'Apollon at the Louvre is an example of magnificence in decoration. The vastness of these rooms combined with the lavish use of marble, plasterwork and painted ceilings, with the addition at Versailles of the famous mirror glass panels, created an effect of overwhelming grandeur.

Among the architects and artists working at this time were Jean Berain (*q.v.*), André Charles Boulle (*q.v.*), Jean le Pautre, Robert de Cotte and Jules Hardouin Mansart (*q.v.*). Their work continued in the period of the régence in which baroque ornament was transformed into the airy, delicate rococo of the mid-18th century. The beginning of this more fluent treatment can be seen in the work of Robert de Cotte at Versailles and the Hôtel de Toulouse, Paris. An immense variety of materials was used for the inlaid and decorated furniture; in a piece by Boulle, for instance, as well as the tortoise-shell and brass inlay, ebony, copper, lapis lazuli, green-stained ivory or horn and mother-of-pearl are employed. De Cotte was followed by the later work of the architect and decorator Germain Boffrand. Typical rococo features are seen in his interiors for the Hôtel de Soubise, Paris (1735), where architectural form has been subordinated to the demands of the decoration; the cornice has disappeared and walls curve into the ceiling, appliquéd with ragged C-scrolls, garlands of flowers decked with ribbons, sprays of foliage, trellising and shell motifs. The reduced scale of rooms and reaction from monumental design result in elimination of the classical orders. Relatively small painted panels, idealizing peasant life in the *fête champêtre*, were enclosed in flattened moldings, silvered or gilt; pastel-coloured backgrounds prevented the smaller size of the salons becoming too evident. The use of Chinese motifs typifies the search for novelty and blends well with the general lightness of style. The Cabinet de la Pendule at Versailles (1738) designed by J. Verberckt is

another excellent example of French rococo. G-M. Oppenord, J. A. Meissonier (*q.v.*) and F. Cuvilliés also were distinguished designers and worked with the best artists and craftsmen of the time.

The rococo fashion spread across Europe to the courts of minor royalties where many Frenchmen were employed to provide up-to-date buildings and schemes of decoration. In France the Gobelins factory became restricted mainly to the output of tapestries; equally fine work is seen in Aubusson and Beauvais carpets and tapestry. Improvement in glass manufacture resulted in larger mirror panels, which reflect their paneled surrounds and brilliant crystal chandeliers.

The Louis XVI or neoclassic style began, in fact, to take root before the death of Louis XV in 1774. From 1748 onward the characteristically French regard for formality was stimulated by the archaeological discoveries at Herculaneum and Pompeii and by the other surveys of classical remains published at this time. It is sometimes forgotten that contemporary English styles also had influence in France, mainly through the published works of Robert and James Adam. The asymmetrical, sinuous lines of the rococo were slowly replaced by a more restrained form of decoration based once again on straight lines, right angles, circles and ovals, arranged symmetrically. The lightness and fine moldings were retained but the decorative forms were once more contained by the architectural framework. New motifs, many of them selected from antique Roman wall painting, decorated the paneling, in paint or in flat relief; palmettes, husks, urns, tripod stands, sphinxes, trophies of arms or of musical instruments were frequently combined in the decorative schemes. Gilt bronze was used with wood and plasterwork for moldings and ornamental fillets, emphasizing the rectilinear character of the design. The work of J. A. Gabriel (*q.v.*) in both the Salle du Conseil at the École Militaire (begun 1755) and the Galerie Dorée, Ministère de Marine (begun 1762) may be cited as Parisian examples. The keynote of colourings as well as designs is refined simplicity. Silk-tapestry wall hangings with fine flower and ribbon motifs appear in pale blues, greens, rose and lilac. Similar colourings were used for satin and velvet upholstery. The fine wood carving of the brothers Rousseau, gilt bronze work by Clodion (Claude Michel) and furniture pieces by David Röntgen, C. E. Riesener and J. F. Oeben show Louis XVI decoration at its highest. Exquisite work can be seen at the Wallace collection, London, and in the boudoir of Madame de Sérilly, now in the Victoria and Albert museum, London, where the carved, painted and gilt decorations of the panels with classical figures and baskets of cascading flowers are by Simon de la Rottière and the marble fireplace with caryatids (statues of women used as supporting pillars) and gilt bronze mountings is by Clodion. Apartments for Queen Marie Antoinette at Versailles and her boudoir at Fontainebleau are full of this extravagant delicacy, soon to be obliterated in the French Revolution. (J. E. Le.; E. C. D.)

3. Spain.—Moorish influence mingled with subsequent western classical styles to produce a unique flavour in decorative design. The style known as Mudéjar (*c.* 12th–17th centuries) was the early outcome of these blended Christian and Arab ideas and consists in essence of tiled floors and skirtings in polychrome, plain white walls, carved stucco friezes and intricately decorated beamed wooden ceilings. The Duke of Alba's palace, Seville, contains a fine example of this style.

Yellow tiles decorated with freehand motifs in blue became common in the 16th century. Fireplaces were seldom used in southern Spain, where tiled ground-floor summer living rooms were vacated in the winter for the upper rooms.

The discovery of the new world, with the riches Spain subsequently drew from Mexico and Peru, created a period of Spanish ascendancy in the 16th century which encouraged building and coincided with the spread of Renaissance ideas throughout Europe. The influence of decorative craftsmen from Italy together with the abundance of precious metal encouraged the development of Plateresque (lit. "silversmith like") decoration. This type of Renaissance decoration was first seen in church interiors, in the form of tombs, *retablos* and ironwork screens. The Italian motifs were used in a totally non-Italian manner, encrusting the surfaces as in Gothic or Mudéjar style.

This unique Spanish blend of widely separate styles produced the fine interiors of the late 15th-century Infantado palace, Guadalajara, by Juan Guas, and the palace at Peñaranda de Duero (*c.* 1530) probably by Francisco de Colonia, where interlaced ceiling beams and timber panels were supported on honeycomb cornices and finely ornamented friezes. (Unfortunately much of this work is now damaged or destroyed.)

Smaller houses as well as palaces were built round a patio, usually colonnaded and with modeled or carved friezes, columns and bracket capitals.

Window grilles or *rejas* often form an important part of the decorative scheme, the ironwork being traditionally of a high degree of excellence. Love of closely patterned decoration, enveloping all surfaces which could easily be carved or modeled, is a foremost characteristic of early Renaissance work in Spain, and of the contemporary Manueline style in Portugal. Similar, if rather coarser, work in this style flourished in the South American colonies, where the subsequent Churrigueresque baroque manner also became well established.

High Renaissance decoration in Spain was influenced deeply by the austere character of Philip II and his vast combined palace and monastery, the Escorial (1559–84) near Madrid. This was built for him by Juan Bautista de Toledo and Juan de Herrera. Ornament is reduced to a minimum; much of the granite of which it is built is left unadorned and frescoed vaulted ceilings are the main features.

A revival of decorative arts took place under the influence of José Benito de Churriguera (1650–1725) and his family and followers. The Churrigueresque, which also remained a peculiarly national style, expressed the baroque feeling of the 17th century in extravagant polychrome. Surfaces were broken into scrolls, rosettes, volutes and fantasticated moldings, bunches of fruit and flowers hung from broken or inverted cornice moldings, and the whole interior, for example the sacristy of La Cartuja, Granada (1727–64), appears to drip with ornament. Here, even cupboards and doors were inlaid with silver, tortoise shell and ivory and the only plain surface is the checkerboard tiled floor. Remarkable among domestic examples of this style is the palace of the Marqués de Dos Aguas, Valencia (1740–44).

Under the Bourbons French and Italian influence increased, as can be seen in the interiors of the royal palace at Madrid (1738–64) with its handsomely painted ceilings and brocade wall hangings. Here also subsequent changes of taste are echoed in the lighter rococo treatment of the Gasparini saloon. Toward the end of the 18th century the neoclassic movement gained a limited footing though regional styles continued to incorporate the baroque and older forms.

Fine examples of Spanish colonial work exist in Mexico, Peru and other South American countries where the baroque was allied, as in Europe, with the Jesuits. Churches are painted and gilded with exuberance equal to, or even greater than, that of the mother country, sometimes encrusted with tiles and always possessing elaborate *retablos*.

4. Northern Europe.—After spreading from Italy to France, Renaissance influence began to filter to Belgium and Holland, later reaching the various Germanic states and finally dying out in Scandinavia and Russia.

In the Low Countries and north Germany during the 16th century Renaissance ornament was adapted to form an entirely individual style which can be seen in the pattern books of Vredeman de Vries and Wendel Dietterlin. Strapwork (interlacing bands and fillets) and raised facetted ornament were widely employed, together with muscular, grotesque masked caryatids and distorted architectural features arranged in undisciplined designs. Chimney pieces, with overmantels carried to the ceiling, were embellished with marble columns and elaborate strapwork patterns, while similar ornaments flanked the doorways and enriched the ceilings. The great tapestries for which the Netherlands had long been famous were still in use and oriental carpets were spread as table covers, and not used on the floors. Many town houses and civic

buildings were comfortably appointed without spectacular extravagances and give an impression of modest prosperity. In Belgium the Musée Plantin-Moretus, Antwerp (1550), is unusually richly decorated, showing the influence of Spanish rule in the use of embossed leather as a wall covering. Large windows, with rectangular leaded lights, are again typical of a northern climate. Ceilings are beamed or plastered and floors most frequently are of tiles on the ground floor and timber on upper floors.

The later styles of baroque and the 18th century tastes are copied from French models, particularly in Belgium. The Dutch, after achieving independence in the latter part of the 16th century, developed their decoration on more individual lines. Typical domestic interiors on a small scale are familiar through the paintings of Jan Vermeer (1632–75) and Pieter de Hooch (1629–*c.* 1684). The fine series of town houses by Daniel Marot (*q.v.*) and his sons in The Hague illustrate the cross currents of the various styles; built at the turn of the 17th century they were conceived in the Louis XIV or régence manner, yet could be set down in 18th century London without incongruity (and Marot did, in fact, work for a time in England). Fine stuccoed ceilings and overdoors, largely uncoloured, and wrought iron balustrading are characteristic.

In Germany the general trend was similar but in south Germany and Austria fresh impetus and individuality were given to baroque and rococo design also. French and Italian craftsmen worked throughout the 17th century on the many Catholic churches built in south Germany, Austria, Bohemia and Moravia. The use of colour, fresco and stucco which they introduced has its own particular flavour when seen in cool northern light.

Secular building from the early 18th century, in the hands of Johann Lukas von Hildebrandt, Johann Fischer von Erlach and others, makes use of much sculptural detail. Windows are round or oval, atlas figures strain to support capitals, balustrades are carved in sculptural manner and modeled niches contain larger than life-sized figures; all these give a feeling of movement reminiscent in its impact of Bernini's work in Rome. In Vienna the Palais Daun-Kinsky (1713–16) by von Hildebrandt and Palais Trautson (1710–16) by von Erlach provide examples of this, also of the enormous staircase hall or *treppenhaus* which is one of the most notable interior features. In the halls, colour was frequently confined to the painted ceilings, giving increased force to the novel and delicious colours of the rooms beyond. A vermilion dado or olive green panels may be contrasted with white and gold. In the Nymphenburg palace, Amalienburg (1734–39), by the Frenchman François Cuvilliés, the rococo reaches its crowning achievement: mirrors are framed in freely scrolled moldings which in their turn are interspersed with trellising, garlands, baskets of fruit and flowers, cupids, birds and fountains in silvered stucco on a pale blue or yellow ground, the whole evoking the essence of pastoral romanticism.

Mingled influences from France, Holland and England reached Sweden and Denmark in the mid-17th century and are seen in the baroque and Louis XIV interiors of the Riddarhuset and Royal palace in Stockholm and in the *chinoiserie* of the later Drottningholm pavilion (*c.* 1760). However, Scandinavian interiors largely continued to be of the traditional exposed timber boarding, hung perhaps with painted linen panels and brightened by woven chair and cushion coverings.

Russia imported foreign designers and styles for the palaces built under the westernizing influence of Peter the Great (1689–1725), his daughter Elizabeth and Catherine II. In the mid-18th century the Italian Count Bartolommeo Francesco Rastrelli, at Tsarskoye (Dyetskoye) Selo, at Peterhof and at the Winter palace, St. Petersburg, and the Frenchman, J. B. M. Vallin de la Mothe at L'Hermitage, each designed largely according to his own current national styles; the same is true of the work of Charles Cameron (d. 1820) at Tsarskoye Selo and Pavlovsk.

In many areas of Europe the Italian Renaissance had little effect on interior decoration. In the Alpine lands, where wood was cheap and plentiful, traditional methods continued for a long time. Wooden floors and ceilings and paneled walls, or partly paneled with plain plaster above, were the general rule. The moldings were bold, but carving was usually in low relief and often the woodwork was painted in bright colours. (E. C. D.)

5. England.—The breakup of the feudal system during the Wars of the Roses and under Henry VII (1485–1509) had far-reaching effects on the social structure of the time and consequently on domestic buildings and their decoration. The new conditions necessitated a larger number of rooms and the great hall, though still an important apartment, was no longer the focus of indoor life. Wider distribution of wealth gave rise to a great number of country houses, and for the next four hundred years the English excelled in their building and decoration.

The Italian style reached England in the early 16th century; the earliest example is the tomb of Henry VII in Westminster abbey, designed by Pietro Torrigiano of Florence at the command of Henry VIII and completed in 1519. For the next 40 years or so English craftsmen borrowed from the repertoire of Italian ornament, at first inspired by and imitating the Italian artists and craftsmen, employed on royal works at Hampton Court palace, Middlesex, and Westminster, London, who used arabesque decoration, medallion heads and *amorini* on paneling and plasterwork, often mingling them with the traditional Gothic motifs. The great hall at Hampton court (1515–30) shows a combination of Renaissance carved and gilded detail with the traditional type of open hammer-beam roof and Tudor mullioned windows. In spite of Henry VIII's example, however, the Gothic style died hard in England, lingering in the remoter districts well into the 17th century.

During the second half of the 16th century, as a result of the break with Rome, the newly created and distinctive Renaissance style of the Low Countries and Germany largely replaced the Italian style since it was fostered by the close religious, political and economic relations between England and the Low Countries, the influx of immigrant workmen and the circulation of Flemish and German pattern books. It became the dominant influence in the decoration of paneling and plasterwork, characteristic features being intricate strapwork patterns, pyramid finials (sculptured ornaments used to terminate gables), raised faceted ornament, masks and caryatid figures, scrolls and pilasters. Both the Italian and Flemish styles were adapted and naturalized to some extent by the English craftsmen producing a new style which is peculiarly English—a style that can be seen in the plaster ceiling at Herringstone lodge, Dorset, and in the decoration of the north drawing room at Levens hall, Westmorland.

At this time, also, the internal porch was introduced into many houses; this device excluded drafts from the room and also in some cases made it possible to reach a second room without passing through the first. Broughton castle, Oxfordshire (*c.* 1625), has a fine internal porch in the drawing room.

The frescoing of walls continued, and of the few remaining examples some show scenes taken from biblical and classical sources and incidents from local folklore. A good Elizabethan example depicting scenes from the story of Tobit was found at the White Swan inn at Stratford-upon-Avon. Embossed, painted and gilt leather was less used in England than on the continent, but tapestries and such woven fabrics as velvet and damask for the wealthy and "sayes" (fabrics resembling serge) and "bayes" (baize) for people of more modest means were widely used as wall coverings. The inventories of Henry VIII's palaces show the vast number of tapestries and various hangings possessed by kings and great men, as does an inventory of 1541 from the Vyne, Hampshire, which lists sets in almost every room of the house, including the chambers of dependents. Hangings of painted cloth were widely used as a cheaper substitute for tapestry and also depicted histories from biblical and classical sources and decorative motifs passing from Gothic to Renaissance subjects. Nearly all of this "counterfeit arras" has perished, but a set displaying the acts of the apostles survives at Hardwick hall in Derbyshire. Also at Hardwick is one of the finest plaster friezes in the country. About ten feet in height, modeled in low relief and coloured with tempera, it dominates the paneled presence chamber with scenes of the hunt, coats of arms and panels depicting spring and summer. In the light of the great windows, which gave rise to the rhyme "Hardwick

hall, more glass than wall," the pale colours achieve a frosted magnificence. The plaited rush matting, which was frequently used as a floor covering in Elizabethan interiors, is also noteworthy.

Great chambers and long galleries, usually on the upper floors, are distinctively Elizabethan and were used in many cases for work and recreation in bad weather. Barrel-vaulted ceilings occupying the roof space often increased the height of the rooms, as at Chastleton house, Oxfordshire (*c.* 1600). The plaster ceilings were treated elaborately; narrow interlaced bands formed geometrical patterns, with semi-stylized floral, arabesque or heraldic motifs in the panels between. At Montacute in Somerset, Aston hall near Birmingham and Knole, Kent, there are fine examples from the late 16th and early 17th centuries; another is in the great chamber at Herringstone, where pelicans and swans, fishes and mermaids are modeled in relief between ribs and pendants of plaster. The steep medieval winding newel stair (stair with central pillar from which steps radiate) in wood or, more often, stone was abandoned for the more spacious staircase with straight flights of stairs, easier in gradient and planned round an open well. This was most frequently constructed of oak, with carved strings, newel posts (the upright terminating a flight of stairs) and balusters (individual columns in a balustrade) making the most of the opportunity offered for decoration and enrichment: one of the finest is at Hatfield house, Hertfordshire (*c.* 1610) and another, where the woodwork is painted, is at Knole (*c.* 1605).

Toward the middle of the 16th century, a feeling for classic reserve was spreading and the late Renaissance period might have flowered under Charles I had not political upheaval checked the zest for fine building. Inigo Jones (*q.v.*; 1573–1652) twice visited Italy and was one of the few north European architects completely to absorb the spirit and decorative repertoire of Italian Renaissance classicism. He introduced the new style in the Banqueting house at Whitehall and the Queen's house at Greenwich; and in spite of the Civil War and the Commonwealth period (1649–60) he and his associate and kinsman, John Webb, built Wilton house, Wiltshire, and possibly Forde abbey, Dorset.

At Wilton the incomparable double cube room (*c.* 1650) shows the nobility of effect Jones was able to achieve in quite a small compass, for the dimensions of the room ($60 \times 30 \times 30$ ft.) are not large comparatively speaking. The basic influence is Italian, but the final result, with wide oak-boarded floor, and white- and gold-plastered and paneled walls designed to accommodate the fine Vandyke portraits, white marble fireplace and Corinthian doorcases, is truly English. The coved and painted ceiling, executed by Edward Pierce and Emanuel de Critz, is less distinguished than the decoration below cornice level but plays a vital part in balancing the proportions of the room. Though Renaissance principles are demonstrated in design such as this, they were not fully developed in the country at large until the 18th century and the advent of the Palladian school of architecture and decoration under the aegis of Lord Burlington.

After the unsettled period of the Commonwealth, the Restoration introduced new baroque influences from the continent. These were fused with the restraining classicism which was still considered to be a new style to produce a successful balance of contrast. The designs of Christopher Wren, though mainly for church and monumental buildings, relied for a great deal of their embellishment on the work of the fine artist-craftsmen such as Grinling Gibbons (*q.v.*), sculptor and wood carver, and Jean Tijou, ironworker, whose work can be seen in close association in St. Paul's cathedral. In many country houses large plain-surfaced oak wall panels provided the perfect foil to the grace and liveliness of Gibbons' carved lime-wood swags, garlands and picture surrounds, which incorporated flowers, fruit, musical instruments, cherubs and monograms. In the words of Horace (Horatio) Walpole, Gibbons "gave to wood the loose and airy lightness of flowers and chained together the various productions of the elements with the free disorder natural to each species." At Petworth house, Sussex, Gibbons' genius may best be seen in the series of picture surrounds, perfectly executed, which date from about 1690. Chimney pieces and doorcases were also decorated in Gibbons' manner and similar floral motifs can be seen on the plaster ceilings at Ham house, Surrey. This house, relatively modest in size, represents without ostentation or extravagance the height of luxurious interior decoration in the late 17th century and incorporates many of the decorative innovations of that time. Among these are the practice of painting wood paneling in imitation of marble or wood graining, and of gilding the moldings. A variety of wall hangings includes tapestry, gilt and painted leather and silk damask; there is also elaborate parquetry.

Paintings of allegorical subjects by James Thornhill and Antonio Verrio ornament some of the more important buildings of the age, including the Painted hall at Greenwich, Wren's additions to Hampton court and the great chamber at Chatsworth house, Derbyshire. The intricate work of Daniel Marot, a French Huguenot who had worked for William III in Holland (see *Northern Europe*, above), had a modest influence on the design of many small fittings and shelved cabinets to display china—the collecting of which was a favourite pastime of Queen Mary. Imported lacquer panels were sometimes used for the paneling of rooms in accordance with the Chinese taste of the period.

In the last years of the 17th century and in the early 18th century the woodworker found his domain contracting. Through the influence of the grand tour and under the patronage of Lord Burlington, Italian influence predominated, the work of Inigo Jones was studied and stone and stucco became more widely used, particularly in larger houses. The influence of the architect spread from the outside of the house to the interior decoration and even to the design of the furniture itself. Where wooden paneling was used, it was set in a simple framework. Pine largely replaced oak, and it was painted green, blue, brown and other colours; walnut and mahogany were occasionally used for paneling. The increased use of stone and marble began with John Vanbrugh, playwright turned architect, who, in his first commission at Castle Howard, Yorkshire (1699), showed an individual and masterly interpretation of baroque, sculptural and yet with a certain grim epic quality. Applied decoration was kept to a minimum, a practice which he followed later at Blenheim palace, Oxfordshire, where the severe and spacious entrance hall with marble-paved floor, ashlar-faced (*i.e.*, faced with thin slabs of hewn stone) walls and columns, wrought-iron gallery railing and frescoed dome is the most impressive apartment in the building.

Stone staircases with wrought-iron balustrading came into common use, and by the latter part of the 18th century had almost entirely replaced the earlier, heavier timber stairs such as those at Wolseley hall, Staffordshire, or Eltham lodge, Kent, which had carved openwork balustrades or heavy timber balusters. In the smaller houses of the early 18th century, woodwork continued to provide the main decorative features. Wall paneling, architraves, window shutters and many chimney pieces in simple painted pine echoed the comfortable elegance of the tall sash windows and well-proportioned rooms. Wealthier classes still employed Italian craftsmen, particularly for stuccowork, and the now familiar repertory of garlands, masks and *putti* was applied not only to the designs of Nicholas Hawksmoor, James Gibbs and other architects of the quasi-baroque group, but also to the interiors of William Kent and the Palladians whose influence became dominant toward the middle of the century. In such houses as Holkham hall, Norfolk, designed in strictly classical manner by Kent in 1734, can be seen the results of extensive travel by both architect and owner. The magnificent entrance hall is again one of the most important rooms, designed on the general lines of a Roman basilica with apse and Ionic side colonnades; the columns and plinth are of variegated alabaster and marble, while the coffered and apsidal ceiling surmounts an elaborately decorated frieze. At Houghton hall, also in Norfolk, Kent designed fine suites of furniture for Colin Campbell's interiors; these pieces are usually gilt, with acanthus scrolls, consoles, heads and sphinxes, feet and legs scrolled or of ball and claw type and upholstery in velvet or silk. The plaster ceilings are by Italian craftsmen, with gilded and painted ornament; the walls are dressed with classical plinth, pilasters and frieze; and pedimented marble chimney pieces contain bas-relief panels above the mantelshelf.

Wall hangings were of tapestry, cut velvet or watered silk and

damask. Elsewhere hand-coloured wood-block printed papers and flock papers were coming into use as an economical substitute.

Although the rococo style never fully established itself in England, many interiors were influenced by the asymmetrical *rocaille* motifs found in the designs of such French decorators as Nicholas Pineau and J. A. Meissonier. The stucco and carved decoration became lighter, more fanciful and more tortuous in design. Though many baroque motifs were still used, they were more delicately modeled and the rococo style was characterized by elaborate patterns of interlacing C-scrolls combined with such naturalistic ornaments as flowers, foliage, shells and rocks, arranged subtly in asymmetrical yet balanced patterns. The plasterwork and carved paneling were often painted in light colours and the detail picked out in gold. The music room from Norfolk house, St. James's square, London, now in the Victoria and Albert museum, London, designed by Mathew Brettingham and completed in 1756, is a fine example. The carved wooden panels are enriched with delicate patterns of scrolled acanthus, shells and garlands of flowers, while the overmantel mirror and the main panels are mounted with fanciful trophies of musical instruments. The fine plaster cornice and ceiling are decorated with similar rococo devices. In smaller houses the new motifs were confined to the chimney pieces and doorcases, the remainder of the room being simply paneled or plastered.

Closely allied to the introduction of the French *rocaille* was the revival of the Chinese taste in a new rococo form, for architects and designers, in search of further novelty, turned again to the east for inspiration. Books on travel and topography, notably J. B. du Halde's *General History of China*, published in Paris in 1735 and translated into English in 1736 gave added stimulus. Pagodas, mandarin figures, icicles and dripping water and exotic foliage and birds reached the height of rococo invention. The Chinese taste was particularly popular for bedrooms, where elaborate chimney pieces and doorcases were set against the background of imported or imitation Chinese wallpapers, and the beds and windows were hung with eastern textiles. One of the most elaborate of these rooms was that at Claydon in Buckinghamshire, but a simpler version may be seen in the room from Wotton-under-Edge, Gloucestershire, now in the Victoria and Albert museum. There Chinese wallpaper is combined with a delicate rococo overmantel which provides brackets for small pieces of oriental porcelain. Window hangings, with carved and gilded pelmets, were becoming increasingly important and at Harewood house, Yorkshire, Thomas Chippendale executed a series of pelmets with mock draperies also carved in wood and coloured to deceive the eye completely.

The Gothic taste, a further variation of the rococo, was peculiar to England at this time. The Gothic revival, engendered by antiquarian scholarship at the turn of the 17th century, later spread to literature and during the 1740s appeared in the more concrete forms of architecture and interior decoration. Both William Kent and Sanderson Miller had made essays in the Gothic taste before 1750, and by the middle of the century the fashion was widely popular and many houses, both large and small, were in part Gothicized, both inside and out. As with the Chinese taste, the products of this 18th-century vogue bore little resemblance to the original medieval models. Gothic details, originally worked in stone, were borrowed, adapted, often mingled with *rocaille* and Chinese motifs, and were executed in wood and plaster. At Strawberry Hill, Twickenham, Horace Walpole, leader of the "true Goths," borrowed the designs of medieval tombs and turned them to designs for fireplaces and bookcases. Though this vogue fell out of general fashion in the 1760s, a few enthusiasts remained who carried the Gothic taste through until it was vigorously revived again in the 19th century.

About 1760 the rococo style, with all its vagaries of taste, began to give way before the neoclassic style, largely inspired and introduced by the Scottish architect Robert Adam (*q.v.*), whose work reflected the newly awakened interest in classical remains. Adam returned from Italy in 1758, and strongly influenced by both Roman architecture and interior decoration, he evolved a new style based on classical precedent, using as ornament a medley of paterae (plate-shaped motifs), husk chains, the ram's head, the formalized honeysuckle and other motifs. His style of interior decoration was deeply influenced by the gay and delicate patterns of arabesques and grotesque ornament that he had seen in various classical remains in Rome, and which had already been copied during the Renaissance by Raphael and others. Adam strongly criticized the Burlington school for using heavy architectural features in their interiors, and replaced them with delicate ornament in plaster, wood, marble and painting, against which, in its turn, criticism was leveled. Much of his work, it may be said, is applied decoration—pretty, but without basic architectural quality. With Adam the despotism of the architect over the craftsman was complete. No detail of decoration or furnishing escaped him; his rapid and precise draftsmanship covered the whole scheme, from the over-all treatment of the walls and ceiling to the decorative details of the pelmets and grates. Even carpets were made to order, and often they repeated or echoed the design of the ceiling, bringing the whole room into harmony, as in the green drawing room at Osterley, Middlesex. Wood was not often left unpainted, and although the joinery was still admirable, the enrichment was frequently in composition or metal inlay. There were specially designed temple-fronted bookcases and the plasterwork was often made a frame for the decorative paintings of such artists as Antonio Zucchi or M. A. Angelica Kauffmann.

At this time cheaper and quicker methods of decoration began to be introduced; a considerable amount of the plaster decoration was cast from molds and a composite imitation marble called scagliola was sometimes used for floors and columns, while cheaper woods were disguised by marbling and graining.

At the close of the century the neoclassic style was further refined, the plaster relief decoration being simplified and lightened. The best of this style, strongly influenced by French decoration, can be seen in the work of the architect, Henry Holland, who enlarged Carlton house, London, for the prince regent and built Sothill in Bedfordshire. Holland, like Adam, was inspired by the classical monuments in Italy, where for some time he maintained a draftsman whose drawings of classical detail Holland incorporated in his plasterwork.

VI. 19TH AND EARLY 20TH CENTURIES IN EUROPE

During the early years of the 19th century the neoclassic style continued in western Europe, becoming even more biased toward the literal interpretation of classical remains. Interest in Roman buildings was coupled with a new enthusiasm for Greek and Egyptian features, the latter as a result of the Napoleonic campaigns in Egypt. In England the work of Thomas Hope, a wealthy amateur architect, gained much attention through the publication of his *Household Furniture & Interior Decoration* (1804). He enlarged and decorated his London home in Duchess street and also his country house, Deepdene in Surrey, with somewhat heavy and pedantic design which was at variance with the general trend of the time but influenced later work.

On the continent of Europe, the Directoire and Empire styles of France were pre-eminent for the first quarter of the 19th century. Subsequently, changing social conditions and the developments of the Industrial Revolution were reflected in a welter of eclecticism and the general decay of design.

In Germany the solid bulk of the Biedermeier style, with its thick curtains, draperies, antimacassars and padded upholstery, gave evidence of material prosperity. Many of these features were to become commonplace in Victorian England, but in the meantime, the Regency style was prevalent and contributed many masterpieces of design. Brighton Pavilion (begun 1815) was built by John Nash for the Prince Regent and has recently been restored. It is described by Ralph Dutton in *The English Interior, 1500–1900* (B. T. Batsford, Ltd., 1948) as "A Chinese interior within a fabulous Indian shell, it showed a light-hearted disregard for architectural ethics which rightly should have culminated in confusion and failure, but the contrary is the case, and the rich decoration and brilliant colouring of the ornaments give a fantastic beauty to the rooms." There is much lacquered and bamboo furniture, blending with Chinese wallpapers, fanciful treatments of palm trees as columns and the most extravagant of crystal chande-

liers. However, in general, the Regency style strove for elegance without extravagance; innumerable smaller houses were built and decorated with fine wrought-iron balustrades on curving stone staircases, pleasing carved wood or marble mantelpieces of modest size, and plain or paneled walls of light colourings, on which the use of wallpaper was becoming more common.

The early 19th-century Gothic revival produced a small number of houses in which the pointed arch, together with fan vaulting and crocketed (carved with foliated ornament) or deeply undercut moldings were used with some taste and discretion although without the charm of Walpole's earlier "Gothick." Toddington manor, Gloucestershire (1829), by Charles Barry (who, with A. W. N. Pugin designed the houses of parliament) and Benjamin Disraeli's house, Hughenden manor, Buckinghamshire, are examples of a style which was used later in the century with much greater ostentation and coarseness of detail.

In the principal European countries, interior decoration grew increasingly heavy and elaborate. Ornament came to be considered synonymous with beauty, and pattern covered every possible surface. The products of industrial manufacture were mostly very crude and their use resulted in loss of refinement; for example, aniline dyes, which are harsh in colour, were first made in 1856 and soon replaced the softer, more harmonious colours. Architects decked out their buildings according to whim in a variety of styles: Gothic, Tudor, Roman, Greek, French, Italian, Egyptian or Indian.

In less ambitious schemes of decoration, brightly coloured wallpapers with bold patterns were widely used, and the white plaster ceilings were relieved by modeled cornices and often also by some central feature, frequently in a coarsened rococo design, which made a background for the elaborate light fitting. Rooms became crowded with furniture, and fireplaces were often mounted with elaborate overmantels, fitted with mirror panels and a multitude of shelves and brackets for the display of knickknacks. Both furniture and fittings were draped in dark-coloured plush with heavy fringes. Varnished pitch pine dadoes, stained-glass windows and encaustic-tiled floors were also popular.

William Morris, through his own firm, made a bold and valuable attempt to reassert some definite standards of taste and craftsmanship in interior decoration, producing, with the assistance of such artists and architects as D. G. Rossetti, Edward Burne-Jones and Philip Webb, furniture, wallpapers and tapestries. His influence was limited because like his contemporaries he looked backward to medieval craftsmanship for inspiration and in doing so refused to accept the possibilities of machine production.

Morris' work had an indirect offshoot in the *art nouveau* style of decoration developed in the 1890s primarily by Henry van de Velde in Belgium, as a result of an attempt to disinter the basic form of architecture from its accumulated ornament. The *art nouveau* movement made use of unconventional free-flowing lines, inspired mainly by plant-growth forms both in structural elements such as columns, capitals and arches and in decoration applied to interior surfaces. Although it created much interest at the 1900 Paris exhibition, it never became very widely established but was one of several leavening agents in the sphere of design; another was the study of Japanese art, whose economy of line was in complete contrast to the prevalent European ideas.

Reaction against overcrowded, fussy interiors gathered strength. Plain interior walls in white or very light colours, natural woods and simple doors and fireplaces were used by the more advanced designers in an attempt to create an original style suited to the changed circumstances of life in the first part of the 20th century.

(J. E. Le.; E. C. D.)

VII. 17TH TO EARLY 20TH CENTURIES IN THE U.S.

The story of the domestic interior in the U.S. and its decoration is inseparable both from its own architectural development and from the story of English architecture and decoration from which it was largely derived even long after the Revolution. Any discussion of U.S. decorative design, therefore, must refer constantly to the architectural ideas which prompted change on both sides of the Atlantic ocean.

1. Early Settlers' Homes.—Contrary to popular legend, the log cabin was not the earliest shelter of the first English settlers. The turfed-over dugout hut of mud-chinked saplings, not unlike the Indian wigwam with the addition of a clay-daubed wooden chimney at one end, was probably the first home of the settlers in both Jamestown and Plymouth.

These primitive dwellings were speedily replaced by frame structures, copying the traditional small house of southeast England. At first a single room was flanked by a massive chimney (where brick soon replaced wood and clay), but a second room was soon added on the opposite side of the chimney. The attic, later expanded into an overhanging second story, was reached by narrow winding stairs between the central entranceway and the chimney stack.

This development in New England is well represented by such vestiges as the Capen house, Topsfield, Mass. (1683). The interior clearly reflects the structure with its massive exposed oak corner posts, beams and joists and its huge open fireplace which served as the cooking and heating centre of the household. Inside walls were usually of undecorated lath and plaster, covering the studs and their clay or brick filling. Room partitions and the face of the fireplace wall were sheathed with horizontal or vertical boarding, frequently featheredged or molded. Windows were small and originally of casement type, with small leaded panes in a wood frame. Small windows with low ceilings were needed to conserve heat in the severe winters. Floors of wide riven boards of pine, smoothed and sanded, replaced the beaten clay of the first shelters.

The furniture, with few exceptions, was simple and sparse. It was decorated with simple carved and turned ornament and touches of earth colours.

By the end of the century homespun textiles were supplemented by imported woven materials in the houses of the more affluent; these were used for curtains, table covers, bed hangings and seat pads. Richly coloured damasks and velvets, enhanced by the unpainted wood and plaster surfaces, were found in puritan New England, and probably to a greater extent among the less austere New York Dutch and the comparatively wealthy tobacco planters of Virginia.

While utensils of crude pottery and wood served the needs of most people, pewter and, to a surprising extent, vessels of silver were among the possessions of the well-to-do. A remarkable quantity of fine silver was produced in the last half of the century by silversmiths such as John Hull, John Coney and Jeremiah Dummer of Boston and Cornelius VanderBurgh and Jacob Boelen of New York. Although based mainly on English models, the work of these craftsmen shows a distinctly individual feeling for form and proportion and a craft skill matching that of their English contemporaries.

In the early dwellings south of New England, brick and stone tended to replace wood as a building material, though many small timber constructions must have been used which have now largely disappeared. In the Hudson region the traditional cottage of the Flemish and Huguenot settlers, long and low with steep pitched roof and extended eaves, became the typical farmhouse. At the same time, the narrow Dutch town house of brick with its stepped gable ends gave New Amsterdam, even after the English occupation, an appearance completely different from that of the English settlements to the north and south.

In the Dutch houses windows tended to be larger and ceilings higher. The early fireplace, with its tiled surround, surmounted with a deep hood, was flush with the wall instead of deeply recessed. Dutch features such as the horizontally divided door, the monumental cupboard or *kas*, the built-in bed, tiling and dishes of Delft ware gave the early New York interior an individuality which withstood English influence until well into the following century.

Similar national characteristics must have distinguished the early Swedish settlement on the Delaware, where the log cabin of pioneer tradition may have appeared for the first time later in the century. But the Swedish contribution was only temporary because the settlement was speedily absorbed by both the Dutch and the English. The early settlements of the English in east Jersey

were mainly founded by migrants from New England who at first designed typical central-chimney houses, but before the end of the century largely abandoned them for the Flemish type of house in the neighbouring Hudson region. The first settlers in Pennsylvania, arriving in Philadelphia at the end of the century, built the type of town dwelling devised for the rebuilding of London after the Great Fire of 1666, and their story belongs to the following century.

In Virginia and the south, scant evidence remains of the early 17th-century house. Bacon's castle in Surry county, Va., with its projecting two-story porch in front and rear stair tower, built in brick about 1660, is all that remains of a colonial version of the small English Jacobean manor, though there must have been several other examples. From surviving evidence and deduction it is believed that paneled walls, carefully designed beamed ceilings and ornamental plasterwork in colour were employed in larger Virginia houses but while the milder climate made loftier ceilings and larger rooms possible, it is unlikely that the ordinary early dwelling differed from its northern contemporary save in its greater use of brick and in placing chimneys at the ends instead of at the centre of the structure.

Among the wealthy the principal articles of furniture were undoubtedly English imports; the more humble settler probably had to make shift with articles of the simplest sort, but as few articles survive from this period, little is known about it. Certainly the scattered or rural character of the southern settlements and their concentration on tobacco planting failed to encourage the early development of skilled crafts found in villages and towns of the northern communities.

2. Pre-Revolution Homes.—During this period the late medieval tradition of design and decoration was gradually replaced by the formal full Renaissance style. Inigo Jones (1573–1652) and Sir Christopher Wren (1632–1723) had initiated and established the new architectural mode in England in the 17th century. By 1720 these innovations, as reflected in the Queen Anne style with its strong mingling of Dutch and Flemish elements, had already crossed the Atlantic.

In New England the traditional two-story "salt box" was at first modified in detail rather than size by the substitution of a double-hung sash for the casement and the replacement of wood sheathing by paneling and trim of more formal design. Houses of the 17th century were often so "modernized." The parlour of the Samuel Wentworth house, Portsmouth, N.H., now in the Metropolitan museum in New York city, is an instance.

Wren's influence is increasingly evident in the tendency to employ symmetrical design around an accented central feature and, particularly in the interiors, in the greater insistence on classic ordonnance in the positions of openings and the arrangement of paneling. Paneling, usually of pine in the north, was generally painted. Relatively deep and strong tones—red, blue, green, brown and yellow—were used either singly or in combination, producing an effective background for the walnut furniture of the period.

Additional colour was introduced by more elaborate use of woven and embroidered textiles, in upholstery as well as draperies. Though woven carpets for floor coverings were rare even at the mid-century, frequently their effect was achieved by stretched canvas painted with allover repeat patterns.

Throughout the colonies furniture became more plentiful and varied. Chairs without arms took the place of stools, the cabriole largely replaced the turned leg and small drop-leaf tables replaced the fixed-frame type. Bedroom furniture became differentiated with the development of the high chest (highboy) and dressing table (lowboy), and later the case-top desk or secretary became the principal ornament of the living room. Tall mirrors with crested tops replaced the small square Jacobean looking glasses, and portraits and prints came into more general use, sharing the wall space with bracketed wall lights or sconces. Artificial light still came mainly from small wick and grease betty lamps, but tallow and wax candles held in sconces, in adjustable metal and wood floor stands or in candlesticks of brass or pewter and occasionally in brass chandeliers were used by the wealthier.

Though domestic comfort was improving, north of Virginia the large formal house or mansion remained a rarity until about 1750. In the south the wealth of the slaveholding planter made it possible for him to copy the early Georgian manor house type. Great houses of two or three stories with side dependencies became numerous. Stratford in Westmoreland county and Westover in Charles City county, built about 1725–30 by the Lee and Byrd families, are early examples of the type. The elaborately paneled rooms of these mansions were furnished according to the latest London fashion. Probably only later in the century were these English pieces mingled with those from the cabinetmakers of Philadelphia, New York and Boston. Between 1750 and the Revolution this Georgian phase reached its highest development. Though generally smaller and lacking the forecourt and dependencies of the southern mansion, the larger houses of the north, such as the Wentworth-Gardner house in Portsmouth, mark perhaps the most distinctive achievements of colonial design and decoration by their apt translations into wood of brick and stone Georgian forms.

In the middle Atlantic colonies, particularly in Philadelphia which by 1760 had assumed urban leadership in the colonies, a type of domestic design midway between that of New England and Virginia had developed. There the English rococo decorative style publicized by Thomas Chippendale in his *Director* of 1754 received its most competent and original interpretation. This is well seen in Philadelphia interiors such as those of the Powel house (1768) and in the work of cabinetmakers such as Thomas Affleck and Benjamin Randolph. By this time mahogany, with its fine grain, receptive to carving and high finish, had largely replaced walnut as the principal cabinet wood. Inspired by this material and the challenge of London design both these Philadelphia craftsmen and their northern contemporaries, particularly John Goddard and Job Townsend of Newport, R.I., brought their art to the highest level of perfection.

During the third quarter of the 18th century, the paneled interior reached its most elaborate form in the colonies. North of Virginia a fully paneled room was exceptional; wood paneling was reserved for the chimney breast and its flanking recesses or cupboards. In Virginia and the south full paneling remained the rule. In both north and south, however, the mantel and its overmantel were emphasized as a decorative unit and the baroque broken pediment became the usual crowning feature of overmantel and doorway. Painted woodwork remained popular, but with softer and lighter tones, tending toward white and gray. Plaster wall surfaces were also painted. Block-printed and painted wallpapers were frequently used in the main rooms and there are indications that fabric wall hangings were used also.

Plaster ceilings completely concealed the floor beams by the second quarter of the century, and after 1750 these were frequently decorated with ornament in low relief in the French or rococo manner and hung with many-branched chandeliers of crystal. Floors of hardwood, occasionally parquetry, were more frequently covered with patterned rugs of European or oriental origin.

During the 18th century imports of printed cottons or chintz in the Indian taste and silk brocades and damasks largely replaced the linen and woolen weaves of earlier days. Upholstered furniture, wing chairs and sofas and elaborate draperies increased still further the richness of the fashionable interior.

At colonial Williamsburg, Va., surviving houses have in many cases been carefully restored and furnished, giving a complete picture of the comfortable, paneled rooms dating from the middle decades of the 18th century.

The craft of the silversmith continued to develop in the 1700s. North of Virginia even the smaller communities supported silversmiths of ability. Judging from the quality and amount of work that survives from Boston, New York, Newport and Philadelphia, a phenomenal amount of silver plate must have been produced and distributed among even the moderately well-to-do. Like the furniture, this silver mainly followed the Queen Anne style and depended upon elegance of form and line rather than ornament.

As in Europe, the growth of tea and coffee drinking encouraged production of suitable silverware and the import of English and oriental porcelains, which required corner and wall storage cup-

boards. Demand was also created for a variety of small movable tables and stands for tea and coffee services.

During this century the German settlers in Pennsylvania added their traditional styles of design to the dominantly English tradition of the colony, the effects being more evident in folk arts than in formal decoration. It was to this style and its development after the Revolution that the first American decorative glass of Henry William "Baron" Stiegel and Frederick Amelung must be credited, as well as most of the decoration on early American pottery.

3. Classic Movement After the Revolution, 1785–1835.—Even after the Revolution English decorative influence predominated in spite of greatly increased contacts with French thought and ideas. Although many leaders like Thomas Jefferson wished to see a complete break with English traditions, the Georgian forms of colonial days persisted in common usage till 1800 or after. By 1785, however, the reaction in Europe against the rather heavy classic style called free Palladianism and its rococo and baroque elaborations began to affect design in the United States.

Jefferson, largely under French influence, became the leader of one aspect of the new movement in the south which combined practical planning with a literal classicism based on the direct study of ancient monuments. While Jefferson's interest in strict classic form was felt particularly in architecture, the decorative phase of the movement both north and south was dominated by the freer and more personal interpretation of classic motifs based on the work of the Adam brothers in England, before and during the Revolution. This was the principal influence in the designs of Charles Bulfinch of Boston and his followers and was popularized about 1800 in the builders' pattern books of William Pain and Asher Benjamin.

The houses of Boston, Salem and Portsmouth built around 1800–10 by or under the influence of Bulfinch and Samuel McIntire of Salem are the best examples of the changes wrought by the fine scale and delicate precision of their Adam-inspired designs, producing what has become known as the early federal style. In the houses of the time the circle, the ellipse and the octagon were introduced as occasional variations in the plan, and the flying or freestanding staircase became a feature of the entrance hall.

In interior decoration wood paneling was practically abandoned or was restricted to the area below the chair rail. Decorative emphasis was concentrated on the mantel and overmantel, the doors and window frames and the cornice, all usually of wood and enriched with delicate repeat ornament either carved or applied. Rich colour in draperies and upholstery was set off by wall surfaces and decoration in light tones, grayed tints or white. Block-printed wallpapers with classical motifs were frequently used, as were stenciled decorations in the simpler homes.

In general, geometric forms and the urn, swag, patera and wreath were employed. The taste for lightness and attenuation which verged on dryness was reflected in the furniture. The designs of George Hepplewhite and Thomas Sheraton influenced by Louis XVI and Directoire forms found American versions around the turn of the century in the work of Samuel McIntire of Salem, John Seymour of Boston, Duncan Phyfe of New York, Henry Connelly of Philadelphia and the cabinet shops of Baltimore and Charleston. At first, light woods and finishes and decorative inlays were preferred, but by 1820 French empire influence substituted dark reddish mahogany, carved and gilded ornament and heavy, often ill-proportioned forms considered more in keeping with classic taste.

The new classicism, particularly in its Adam phase, was echoed also by the silversmiths, among them Paul Revere, whose patriotic activities have given him a prominence somewhat unfair to his able colleagues. This silver is identified by its general use of the urn form, relieved occasionally by the cylinder, and by a simple elegance of silhouette enriched only with surface chasing. After 1820 the early federal style waned and Jeffersonian classicism was modified by the introduction of Greek and even Egyptian detail, constituting the so-called Greek revival. Accompanied by furnishings and draperies in the heavier Sheraton-empire taste, the classic pattern established in the 1820s became the basic style in building and decorative design until about 1850, and constituted for the time a national style without parallel in Europe. In its later decorative aspect the Greek revival became a fashion rather than a style. As such it marks not only the end of the 18th-century classicism but the beginning of the romantic movement.

4. The Romantic Movement and the Battle of the Styles, 1835–1925.—The ordered symbolism of the Roman classic style had been envisaged by Jefferson as a proper expression of the American national ideal; but by 1835 its restraints had grown tedious. Social and economic changes already initiated by the Industrial Revolution encouraged reaction. This found more or less romantic and emotional expression in a series of style revivals ill-adapted to actual conditions.

The Greek revival, stimulated by the Greek struggle for national independence, was diluted almost immediately by the antiquarian romanticism of the "Gothic," "Tuscan" and "country cottage" fashions. These offered opportunity to the undercurrent of practical utilitarianism, repressed or thwarted by the classic formula, and also gave a fertile field for the novel or exotic in decorative taste fostered by a wealth-induced appetite for comfort and display. By the middle of the century the last vestiges of order in early Victorian romanticism had disappeared under a plethora of decorative motifs and objects easily and inexpensively produced by machine. Colour became confusedly drab or brilliant, and generally out of character as a result of the introduction of uncontrolled chemical dyes and the magic of the Jacquard loom. Increased travel and ease of communication made American styles hardly distinguishable from those of Europe.

This decorative salad of classic and medieval motifs was supplanted by the revival of 18th-century forms which temporarily triumphed in the "second rococo" of the 1850s when rosewood and walnut took the place of mahogany. This was succeeded by fashions based on the 17th century and the later Renaissance until the Centennial exhibition of 1876 brought to America the "craft" medievalism, advocated and industrialized by Charles Eastlake, and a new series of more literal style revivals including that of colonial times. These in turn absorbed the oriental influence of the "aesthetic" movement of the later 19th century.

In the first quarter of the 20th century this confusion culminated in antiquarianism for the wealthy and, for most people, period reproductions provided by the wholesale decorator and manufacturer. These 90 years of enormous technical and financial development are too confused and complex for further analysis here. Almost from the beginning, however, a body of criticism and rational experiment was developing both in Europe and America which was to find effective expression in the early 1920s amid the social and economic upheavals following World War I.

VIII. THE MODERN MOVEMENT

The struggle between the desire to cling to tradition and the necessity of accepting a society based on mechanized industry came into the open between World War I and World War II. The aim of the Bauhaus group, established in Dessau, Ger., in the early 1920s, was to adapt industrial techniques to meet the needs of a society impoverished spiritually and materially by war. Their work was the culmination of the numerous reform movements of the late 19th and early 20th centuries; cathartic and analytical in its methods, on one hand it shocked the conservative into immoderate fury and on the other converted its radical adherents into equally uncompromising iconoclasts. Many of the "functionalist" ideas they employed were inspired by the subtle simplicities of the Japanese tradition and by the innovations and writings of the Chicago, Ill., architect, Louis H. Sullivan. Functionalism demanded a complete break with the ornamental motifs of the past and a quickened response to form, proportion, line and texture. It also aimed at a scientific study of human behaviour, correlating psychological responses to physical stimuli of all kinds. The acceptance of its thesis ran parallel to the growth of interest in abstract art and although the uncompromising application of so intellectual a program proved immediately impracticable, its bold challenge to convention resulted in notable changes in interior decoration.

German functionalism was slow to establish itself in Europe and hardly affected American design until its leaders found refuge in the United States from nazi oppression. There the movement was brought to public attention in the mid-1930s by the need for new stimuli in the trough of economic depression, by the educational campaigns of the Museum of Modern Art in New York city, and by the re-establishment of the Bauhaus teachings in the Institute of Design in Chicago.

In the decade following the International Exposition of Decorative Arts held at Paris in 1925 progressive western design was influenced principally by the less radical productions of the French luxury crafts, based on a modified *art nouveau*, and the Swedish success in combining and developing craft traditions in co-operation with industry. These influences were, however, confined to relatively small and semiprofessional coteries while the market as a whole continued to concentrate on traditional forms, producing and adapting them at various levels of quality and taste. By 1935 the functionalist movement, lead by the disciples of the Bauhaus program, had gained a substantial following among the younger architects and designers. During World War II development virtually ceased in most European countries, and subsequently attention turned again to the Scandinavian countries, particularly Sweden, where strict consideration of function led to simple furnishing schemes which relied on natural wood grains, clear colouring and texture for their effect. Pattern was subdued and, where used, uncomplicated in outline.

Meanwhile in the U.S. during and after World War II, the functionalists, still with the help of the museums and the more progressive schools and periodicals, had gained the interest of a considerable proportion of both the wealthier members of society and the manufacturers who catered for them.

The most obvious changes due to the functionalist movement were: firstly, rapid mechanization; secondly, redistribution of interior space; and thirdly, elimination of formal barriers between indoors and outdoors. These developments, most prevalent in the United States but disseminated throughout much of the world, were accompanied by radical changes in decoration and the design and use of furniture and fittings which came to be known as "International" style. Equipment for heating and lighting, sanitation and food preparation, all derived from inventions of the 19th century, were brought to a high degree of mechanized efficiency taking full advantage of advanced production methods. Since convenience and economy became principal considerations, utility units were fitted into living space instead of being hidden in otherwise unused areas, as in the traditional room arrangement. By insisting on simplicity of form, colour and texture they were made to obtrude as little as possible. In particular the appearance of the kitchen was studied carefully, especially in smaller houses.

Under the influence of electric power, liquid fuels, flexible controls of temperature, ventilation and lighting and countless labour-saving devices, the mid-20th century house began to evolve into an efficient "machine for living."

Reconsideration and correlation of the space needed in living areas broke down traditional room divisions. The new interior, with its invitation to movement, both actual and implied, was in harmony with the times. Decoration became concerned with function and because a living area served more than one purpose, it was frequently irregular in plan and impossible to treat as a unit in the traditional formal manner. Changes of colour, texture and materials consequently became the chief resources of decorative design, taking the place of ornament. Earlier attempts at the functional mode suffered from too much anxiety over simplicity and unity, and consequently became monotonous and cold.

The demands of space made it necessary to keep movable pieces of furniture to a minimum and encouraged the use of built-in units. An earlier overemphasis on straight lines and angles was countered by greater use of curved and molded forms in furniture design. As the average house became smaller and more efficient in its use of enclosed space and as the desire for outdoor living grew, there was a tendency to replace at least one of the enclosing walls of both living and bedrooms with glass. With a well-arranged plan this gave each room an ever-changing mural and better light and it also extended the apparent size of the interior. The illusion of bringing the outside indoors gave a feeling of freedom but it also created certain practical and psychological problems.

By the 1960s a certain reaction against plain-coloured surfaces was taking place, particularly in France, England and Italy where popular taste had never accepted the strictly functional approach. Multiplication of synthetic materials for furniture and decorative surfaces allowed a great variety of choice in achieving new effects, not always with happy results. (M. R. Rs.; X.)

INTERLAKEN, a Swiss town in the canton of Bern, so called from its position on the flat plain (*Bödeli*) 593 m. (1,864 ft.) above sea level between the lakes of Brienz (east) and Thun (west). Interlaken is built on the left bank of the Aare and grew up round the convent of Augustinian canons, founded about 1130 and suppressed in 1528. Pop. (1960) 4,738 (mainly Protestant and German-speaking).

In the surviving buildings of the convent religious services (Anglican, Scottish Presbyterian and French Protestant) are now held, while the castle (1750) is occupied by offices of the cantonal government. The fine, well-shaded avenue called the Höheweg runs through the main portion of the town and is lined on the north side by a succession of hotels and the large Kursaal and on the south side by the Höhe Matte pleasure ground.

Interlaken (with its suburbs Unterseen and Matten) is much frequented in summer, partly because of the glorious view of the Jungfrau which it commands to the south, and partly because it is the best starting point for many excursions, as to Schynige Platte, Lauterbrunnen, Grindelwald, Mürren and Jungfraujoch. The lines serving these places all start from the eastern railway station (that from Thun reaches the western or main railway station), whence steamers depart for the Giessbach falls, Brienz and Meiringen, on the way to Lucerne or to the Grimsel and Susten passes. Opposite Interlaken on the other side of the river is Unterseen (pop. [1960] 3,783) which was built in 1280 by Berthold von Eschenbach.

INTERLOCUTORY DECREE, generally a judicial decision that is not final or that deals with a point other than the principal subject matter of the controversy at hand. An interlocutory decree of divorce or, in England, a decree nisi, is a judicial decree pronouncing the divorce of the parties provisionally but not terminating the marriage until the expiration of a certain period. The purpose of requiring such a period of time after the pronouncement of the divorce is to discourage quick and easy divorce, to encourage reconciliation, to enable the court to supervise the arrangements to be made for the children of the marriage, and also, in England, to give the queen's proctor an opportunity to discover collusive practices by which the parties may have deceived the court.

In England, under the Matrimonial Causes act, 1860, the period required to expire between the decree nisi and the decree absolute was three months; under the act of 1866, six months. In 1946 the period was reduced to six weeks; under the Matrimonial Causes General Order, 1957, it was restored to three months. In the United States about ten states require that a decree of divorce absolute be preceded by an interlocutory decree, the period of delay varying from three months to one year. *See* also DIVORCE.

INTERLUDES. Early Tudor dramas, performed indoors and before a select circle by professional minstrels (*lusores*) or amateurs (such as Thomas More in his youth) in the pauses of some other entertainment (banquet). Interlude may also mean simply a "play between persons" (*ludus inter personas*), hence stage play in general. Most interludes were of a nonreligious and even farcical nature. However, in the 15th and 16th centuries some plays were called interludes which are today classed with the morality genre. Allegorical machinery such as associated with the moralities is not absent in *A Goodly Interlude of Nature* by Henry Medwall (*q.v.*) and in his revival of the old *débat, Fulgens and Lucres* (*c.* 1497). Medieval abstractions prevailed in *A New Interlude and a Mery of the Nature of the IIII Elements* (*c.* 1517) attributed to John Rastell (*q.v.*) and in John Redford's *Wyt and Science* (*ante* 1548). Rastell's son-in-law, John Heywood (*q.v.*), brought the interlude genre to perfection in his "newe and very mery interludes" called *The Play of the Wether* (*c.* 1533) and *The Play Called the Foure PP* (*c.* 1544).

INTERMETALLIC COMPOUNDS. The formation of intermetallic compounds cannot in general be interpreted according to the laws of ordinary chemistry; progress in the theory of the solid state and the structure of crystals, however, enables the main factors involved to be understood. During the period following the application of microscopic techniques to metallurgical problems and the application of phase-rule principles to metallic equilibrium, much research was devoted to systems consisting of two or more metals. The phase rule, which was based on thermodynamics, enabled the number of distinct phases or types of material which could coexist in such systems to be related to the temperature and pressure at which the systems were studied (*see* THERMODYNAMICS). It became possible to construct for these systems "equilibrium diagrams," that is, diagrams summarizing the temperature ranges and composition ranges over which various metallic phases of the systems were stable at atmospheric pressure. It was quickly realized that metals were able to dissolve in each other, not only in the liquid state but also in the solid state, particularly at high temperatures. Further, it was found that many metals formed well-defined solid compounds with each other. For example, magnesium will dissolve tin to a maximum of about 15% by weight in the solid state. Magnesium and tin also form a stable intermetallic compound, which is of substantially fixed composition and has the formula Mg_2Sn. The melting point of this compound is higher than those of either of the component metals, and its properties are very different from those of either magnesium or tin. The data available for this metallic system may be summarized in the form of the equilibrium diagram shown in fig. 1. At temperatures above the curve ABCDE, all

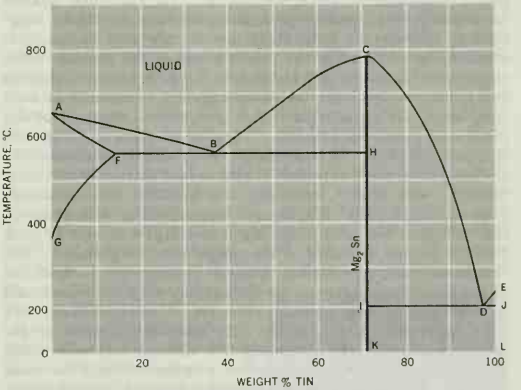

FIG. 1.—EQUILIBRIUM DIAGRAM OF THE MAGNESIUM-TIN SYSTEM

compositions consist of a homogeneous liquid mixture of the two metals. At compositions and temperatures within the area AFG, the system consists of a homogeneous solid solution of tin in magnesium. At temperatures and compositions within the area GFHI, however, the alloys consist of two phases—the solid solution of tin in magnesium and the compound Mg_2Sn. Similarly, alloys in the area KIJL consist of two phases—the compound and the solid solution of magnesium in tin. Only at the precise composition represented by the line CHIK do the alloys consist entirely of the intermetallic compound. The areas ABF and BCH represent compositions and temperatures at which the homogeneous liquid is in equilibrium with the solid solution and the compound respectively, while in areas CDI and DJE the liquid is in equilibrium with the compound and the tin-rich solid solution respectively.

Naturally the attempt was made to interpret compound formation between metals in terms of the valency conceptions of chemistry (*see* VALENCE). This met, however, with only partial success. Although the formation of Mg_2Sn, for example, could be explained in terms of ionic attraction between doubly charged positive magnesium ions and tetravalent negative tin ions, other cases, such as Cu_2Mg and $CuMg_2$, defied such an interpretation. The accumulation of data with respect to intermetallic compounds showed that it is only in a comparatively limited number of cases that the laws of ordinary chemistry can be applied. In the greater number of cases, factors other than chemical bond formation are dominant. Advances in the theory of the solid state, and particularly of the metallic state, have elucidated some of these factors. In addition, the application of X-ray crystal structure determination techniques has revealed the ways in which atoms may be arranged in solid crystals and a satisfactory classification of intermetallic compounds became possible. At the same time, theoretical work tended to emphasize that there is no sharp dividing line between the various types; the problem of fitting unlike atoms together in such a way that the assembly forms a regular three-dimensional framework in space (or space lattice) must be viewed as a whole. The stability of the arrangement will depend on a number of factors. Where these factors oppose each other, classification is difficult, and many cases of behaviour intermediate between those of the well-defined compound types are known.

The discussion of the main types of intermetallic compounds observed may well begin with the compounds in which the normal valencies of the component metals are satisfied. These are only found when the electrochemical characteristics of the metals differ considerably. Just as the electropositive metals of the alkali and alkaline earth groups of the periodic table form stable compounds (salts) with the electronegative elements of the halogen group, they tend to form stable intermetallic compounds with the more electronegative of the metallic elements. There is a general tendency, therefore, for metals of the alkali and alkaline earth groups (*e.g.*, sodium, potassium, rubidium, beryllium, magnesium, calcium) to form stable compounds with silicon, germanium, tin and lead in the fourth group of the periodic table, and arsenic, antimony and bismuth in the fifth group. Selenium and tellurium also form the electronegative component in such compounds. In compounds of this type, normal valencies of the component metals are satisfied. A typical selection of compounds is found in the alloys of magnesium. With silicon, germanium, tin and lead, one stable compound is found in each case. Alternatively, in alloys with arsenic, antimony and bismuth, the compounds Mg_3As_2, Mg_3Sb_2 and Mg_3Bi_2 are formed, while with selenium and tellurium, the compounds MgSe and MgTe occur. In each case the normal valencies of the components are satisfied. The compounds have very limited ranges of homogeneity (a reflection of the high affinity between the metals), are very brittle and tend to have high melting points. They are, if not insulators, very poor conductors of electricity. The stability decreases as the atomic number of the electronegative element increases within any one group of the periodic table, in agreement with the usual tendency for the elements of any one group to become progressively more positive in character as the number of the period to which they belong increases. This is reflected in the progressive decrease in melting point on passing from Mg_2Si (melting point 1,102° C.) to Mg_2Pb (m.p. 553° C.), and from Mg_3Sb_2 (m.p. 1,228° C.) to Mg_3Bi_2 (m.p. 823° C.). These compounds are also characterized by high heats of formation, which are of the order of several kilocalories per gram atom. In general, the greater the stability and the heat of formation, the greater also the electropositive nature of the first metal, and the greater the electronegative nature of the elements of the fourth, fifth or sixth group of the periodic table.

It is significant that compounds of this type have crystal structures which are very closely related to those of true salts. Thus Mg_2Si, Mg_2Ge, Mg_2Sn and Mg_2Pb are anti-isomorphous with calcium fluoride (fluorite, or fluorspar), the arrangement of atoms in the structure of which is shown in fig. 2; the term "anti-isomorphous" means that the crystal structures of the compounds are such that the positive component (Mg) occupies the type of position in the framework or lattice which is occupied by the negative component in the salt. Similarly, the compounds with arsenic, antimony and bismuth are anti-isomorphous with certain of the oxides of the rare-earth elements, while MgS and MgSe and many other tellurides and selenides possess the same type of structure as sodium chloride.

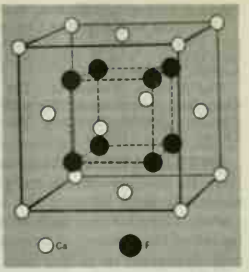

FIG. 2.—FLUORITE STRUCTURE

These compounds may thus be regarded, from one point of view, as the extension of the ordinary ionic structure into the realm of intermetallic structures where one component is electropositive and the other electronegative.

There are examples of a somewhat analogous type of compound to be found among the sulfides, selenides, tellurides and arsenides of metals such as zinc, cadmium and mercury, where the electrochemical differences are less marked than in the systems previously considered. Many of these compounds crystallize in the lattices characteristic of the two naturally occurring forms of zinc sulfide, which are both simply related to the lattice of diamond (fig. 3). Each atom in these compound structures is tetrahedrally surrounded by four atoms of the other component. Diamond takes up this structure by each carbon atom sharing one of its four valency electrons with each of four neighbouring atoms; the bonding force is covalent (electrons shared), and there are four valency electrons per atom in the structure. In the intermetallic compounds which have the zinc sulfide structures, there are again four electrons per atom, as, for example, in CdS, AlP and MgTe. It is very probable that such compounds are not essentially ionic in nature, but are held together by covalent bonds.

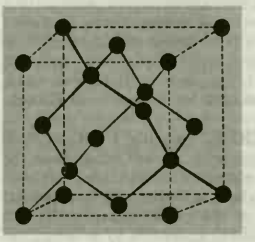

FIG. 3.—DIAMOND STRUCTURE

There is, however, another large class of intermetallic structures which cannot be simply related to ordinary chemistry. These tend to occur in cases where the electrochemical characters of the components do not differ greatly. They often have considerable ranges of homogeneity, are metallic in their general properties and are metallic conductors of electricity. The compositions over which they are stable frequently include compositions corresponding to simple atomic ratios, but these ratios rarely bear any relation to the usually accepted valencies of the components. Thus, intermediate phases occur in the copper-tin alloys at compositions in the region of Cu_5Sn, $Cu_{31}Sn_8$ and Cu_3Sn. At first sight, there appears to be little reason why such peculiar atomic ratios represent stable structures. Systematic work on many alloy systems formed by copper, silver and gold with elements of various valencies, however, enabled phases of this type to be classified, with striking results. In many of these systems, the primary solid solution is followed, as the concentration of the solute is increased, by a phase the structure of which is body-centred cubic (*see* fig. 4); the phase may be stable at room temperature or only at high temperatures. Taking copper as a typical solvent metal, and zinc, aluminum and tin as solutes of valencies 2, 3 and 4 respectively, there are body-centred cubic phases in the regions of the compositions CuZn, Cu_3Al and Cu_5Sn respectively. The common characteristic in each case is a ratio of three valency electrons to two atoms. Both the compositions of the phases and the structure they assume are therefore governed by the valency electron/atom ratio. The same principle holds for many other body-centred cubic phases in this class of alloy. In the alloys of copper and silver with elements of various valen-

cies, homogeneous phases with a complex structure (the "γ" structure) based on a deformed body-centred cube are very frequently found at a ratio of valency electrons to atoms of 21/13. Examples of this type, which tend to be brittle and silvery in colour, are Cu_5Zn_8, Cu_9Al_4 and $Cu_{31}Sn_8$. A further class, all members of which possess a close-packed hexagonal structure, tends to occur at a valency electron to atom ratio of 7/4, as, for instance, in the cases of $CuZn_3$, Cu_3Sn and Ag_5Al_3. It is of interest to note that alloys of transitional metal solvents with similar solute metals also form intermediate phases of the same type. Thus, the phases which occur close to the compositions CoAl, NiAl and FeAl are body-centred cubic in structure, while the phases Co_5Zn_{21}, Fe_5An_{21} and Ni_5Zn_{21} have the "γ" structure. It will be noted that the electron/atom ratios for these phases are the same as in the corresponding copper alloys if the transitional metal atoms are regarded as contributing no valency electrons to the structure, a behaviour which is connected with their peculiar electronic structure. This class of intermediate phase, the formation of which is governed by the number of valency electrons per atom, is usually known as the electron compound class, and occurs in the absence of any marked electrochemical difference between the components and where the atomic sizes of the components do not differ too widely. This class is of great theoretical interest, and its occurrence has been interpreted in terms of the modern electron theory of metals. Broadly speaking, the occurrence of electron compounds is caused by the tendency of a metallic structure to assume such an arrangement that the relatively free (*i.e.*, nonionic) electrons possess the lowest possible energy; this condition is satisfied at electron/atom ratios of 3/2, 21/13 and 7/4 by the body-centred cubic, "γ" and close-packed hexagonal structures respectively. As stated above, these phases frequently have considerable homogeneity ranges, unlike normal valency compounds, and the precise details of the way in which a phase of the fundamental electron/atom ratio can tolerate an excess or deficit of one kind of atom depends on subsidiary factors, such as the atomic size difference involved. It is clear, however, that, in agreement with theoretical expectations, the homogeneity ranges decrease as the valency of the solute increases.

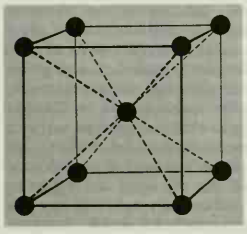

FIG. 4.—BODY-CENTRED CUBIC STRUCTURE

It is important to note that electron compounds are found in ternary alloy systems. Thus the typical "γ" structure is obtained in copper-zinc-aluminum alloys if the composition is so adjusted as to maintain the required electron/atom ratio of 21/13. A further point of interest is that, although the arrangement of the atoms on the lattice points in many electron compounds is entirely at random, in others an ordered arrangement exists. The copper-zinc β phase shows both types of behaviour. At high temperatures, the copper and zinc atoms are distributed at random on the lattice points, and there is no distinction between the atoms at the cube corners and the cube centre of fig. 4. At low temperatures, however, the zinc atoms occupy the cube centres and the copper atoms the cube corners (or vice versa). This behaviour depends on factors, such as atomic size, which are distinct from electronic considerations.

The two types of intermediate phases so far considered indicate that, where size and electrochemical differences are not marked, electronic factors tend to control the occurrence of compounds, while a pronounced electrochemical difference leads to the formation of normal valency compounds. Certain details of the occurrence of the electron compounds, such as the existence of ordered arrangements, show that atomic size differences must be considered as another factor which may become predominant in certain cases. It is known, for instance, that several intermetallic compounds crystallize in the body-centred cubic structure (*e.g.*, NaTl, LiIn, LiZn) without any possibility of an electron/atom ratio of 3/2 being established. In these cases, the effect of size relationship is predominant, and the formation of a large and interesting group of phases is governed primarily by this factor. Among the most interesting are the interstitial compounds, in which it is possible to fit very small atoms into the interstices of a metal lattice, which may be deformed but is left otherwise essentially unchanged. Compounds of this type are met with in the hard, high-melting borides, carbides, nitrides and hydrides of many metals, and the skeleton of the metallic structure accounts for the metallic properties shown by many of these compounds. A large number are based on the face-centred cubic structure (fig. 5). Very small atoms, such as hydrogen, may be inserted into the centres of the small cubes of fig. 5, so that each is surrounded by four symmetrically suited metal atoms; several hydrides possess this structure. The somewhat larger nitrogen and carbon atoms are in general too large to form stable structures of this type with most metals. Such atoms, however, can be inserted into the spaces between metal atoms which occupy the corners of the large cube in fig. 5, and are then symmetrically surrounded by six metal atoms; this type of structure is often observed in carbides and nitrides. Other types of interstitial compounds are known, but in most cases can be understood in terms of the insertion of a small atom into spaces in the metallic lattice which are large enough to accommodate them without too much strain, but not so large that the small atom would be loose in a hole too large for it. The structures are thus determined essentially by the atomic size relationships.

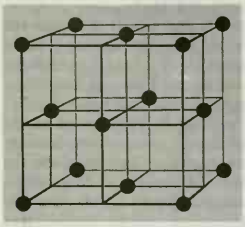

FIG. 5.—FACE-CENTRED CUBIC STRUCTURE

Analogous behaviour is often shown in cases where the atomic size difference is considerable, but not large enough for interstitial compound formation. For instance, the compounds $NaPb_3$, $CaPb_3$, $SrPb_3$, $CaTl_3$, $CaSn_3$ and $CeSn_3$ all crystallize in the structure of fig. 6. In each case the relationship between the sizes of the larger and smaller atoms is similar and the structure appears to be based on geometrical convenience—the structure of fig. 6 is a stable manner in which atoms, the sizes of which differ in a particular way, can be packed together. This clearly suggests that other structures will be found to be characteristic of different size ratios, and this is fully borne out in practice. Thus an approximately constant atomic size ratio is shown in the series of compounds Cu_2Mg, W_2Zr, KBi_2 and Au_2Bi, all of which crystallize in the same type of structure; and it may be noted, in confirmation of the principle that the relative atomic size is the main factor, that the structure of KBi_2, where the bismuth atom is the smaller, is the same as that of Au_2Bi, where the bismuth atom is the larger. The class of body-centred cubic structures quoted above (NaTl, LiIn, LiZn) are also governed primarily by size relationships. Where, in the systems AB and CD, the ratio of the atomic sizes of A and B is closely similar to that of C and D, compounds of the same general type and crystal structure may be expected. Such compounds have narrow ranges of homogeneity because of the difficulty of satisfying the geometrical conditions except at one, particular, simple atomic ratio. For the same reason, ternary compounds of a corresponding type are relatively scarce. Some, however, are known.

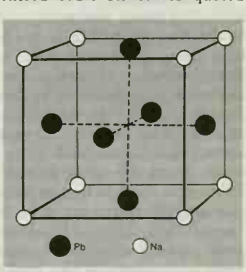

FIG. 6.—$NaPb_3$ STRUCTURE

A particularly interesting group of compounds, in which both size and electronic factors are involved, is illustrated by certain compounds formed between magnesium and zinc, copper or nickel. Thus, in $MgZn_2$, $MgCu_2$ and $MgNi_2$ the ratio of atomic diameters lies between 1.13 and 1.15, and in each case the smaller atoms may be regarded as situated on a close-packed lattice from which

each large Mg atom has replaced two small atoms. There is a close similarity between the three lattices, which are built up from similar atomic planes arranged in a different order. As a consequence of the arrangement of planes, $MgCu_2$ has cubic symmetry, while $MgZn_2$ and $MgNi_2$ are hexagonal, the axial ratio of the latter being twice that of the former. Which of these structures is taken up depends on the number of valency electrons per atom. This is seen most clearly by considering the ternary phases which are isomorphous with these binary structures. Thus, the addition of aluminum to $MgCu_2$ increases the electron/atom ratio and leads to the appearance of a compound with the $MgZn_2$ type of structure, while the addition of silver to $MgZn_2$, which decreases the electron/atom ratio, gives a compound with the $MgCu_2$ type of lattice. These compounds form examples of a type in which the occurrence and general structure are dictated by size considerations, while details depend on number of electrons per atom.

It is possible, therefore, to interpret the formation and nature of intermetallic compounds in terms of three main factors: atomic size relationships, normal valency of components and the ratio of valency electrons to atoms. Although, in this article, only the main types which occur when one or another of these factors predominates have been considered, it will be realized that there must be cases where two or more of the factors are of equal importance. In such cases, more complex compounds may occur, but a discussion of these is beyond the scope of the present article.

Similarly, cases exist where intermetallic compounds of different characteristics crystallize in structures which are essentially the same, or vary only slightly. Thus cobalt sulfide, CoS, crystallizes in a structure in which the metal atoms may be regarded as occupying, in a regular manner, interstices in a close-packed hexagonal arrangement of nonmetal atoms.

The compound AuSn adopts the same type of structure, but with a much smaller axial ratio; it is considered that direct interactions between the gold atoms may be responsible for the difference. The existence of intermediate types, which can be considered from different points of view, does, however, emphasize that the problem of intermetallic compounds must be considered as a whole, without too rigid an insistence on subdivision into types. The classification is a matter of convenience rather than a consequence of the existence of completely different types of compound.

INTERMEZZO, an Italian musical term (in English, interlude, in French, *intermède*) used originally in the 16th century to describe the madrigals and ballets performed between the acts of a play. These intermezzi, or *intermedii*, were written by the finest composers of the time, an early example of them being those in the comedy *Calandria* by Bernardo Cardinal Bibbiena given at Urbino in 1513. In the 18th century an intermezzo was a scene of comic relief, usually for soprano and bass, introduced into the *opera seria*. Giovanni Battista Pergolesi's famous and influential comic opera, *La serva padrona*, was originally a series of such intermezzi, and was first performed in 1733 to provide comic relief during the performance of his serious opera *Il prigionier superbo*. Operatic intermezzi of this kind were so successful that they were later performed as comic operas complete in themselves. The term intermezzo was also used in the 19th century as the title of character pieces, usually for piano, similar in style to a fantasia, an impromptu or a capriccio, of which there are examples by Schumann and Brahms.

INTERNAL-COMBUSTION ENGINE. In an internal-combustion engine a fuel-air mixture is burned so that the hot gaseous products exert a force on moving parts of the machine, doing useful work and generating power. These engines comprise one group of what are known as heat engines, so named because they derive their power either directly or indirectly from an exothermic reaction, such as combustion.

In the internal-combustion engine the products of combustion act directly on pistons or turbine rotor blades, whereas the external-combustion engine employs a secondary working fluid that is interposed between the combustion chamber and the power-producing elements. All heat engines other than the internal-combustion engine are similar in principle to the steam-engine-and-boiler combination in that the fuel with which they operate is burned in a furnace external to the engine; a portion of the energy liberated is transferred through boiler or heat-exchanger walls to a secondary working fluid, commonly water; and the water is converted into steam under a high pressure created by the vaporization. The steam is then conveyed through pipes to an engine in which the pressure of the steam acts upon pistons or turbine runners whose motion causes a shaft to move and produce power.

Fundamentally, the steam engine operates with a high-pressure working medium produced by utilizing the expansion accompanying the vaporization of a liquid; the internal-combustion engine utilizes the large volume of high-temperature combustion products which, when confined, become a high-pressure gaseous medium.

History.—Attempts to devise heat engines were made in pre-Christian times. The steam engine, however, became the first successful type when James Watt carried the ideas of earlier experimenters to practicability during the 18th century. The internal-combustion engine followed as an improvement over the steam engine.

The internal-combustion engine cannot be attributed to any one inventor. The piston, for example, is thought to have originated about 150 B.C., and was used by metalworkers in pumps for blowing air. The problem of preventing leakage between the piston and cylinder wall led Watt to employ rope yarn impregnated with mutton tallow as a packing in 1764. Brass sealing rings were fitted to steam-engine pistons in Scotland several years later.

The internal-combustion engine of the mid-20th century was made possible by a gradual accumulation of knowledge of thermodynamic principles, mechanical skill, availability of materials and experience. The development was inspired by recognition of the disadvantages of steam power plants—their low thermal efficiency, great weight and bulk and inconvenience of operation—all of which are largely traceable to burning the fuel in a furnace separate from the engine. The greater desirability of a self-contained power unit was evident. A remarkable development resulted from the application of engines to automobiles and airplanes. (This development is even more remarkable in that the gasoline engine is poorly suited for propulsion and must have intricate clutch and transmission devices to adapt it for this purpose. The steam engine can be started under full load, but the internal combustion engine must be set in motion by a cranking device before any load can be applied, and its performance is greatly affected by the speed at which it runs.)

The events leading to the development of a practical internal-combustion engine probably start with the attempt of the Abbé Jean de Hautefeuille in 1677 to pump water by the combustion of gunpowder. The vacuum formed by cooling the hot gaseous products was used to operate the pump. Christiaan Huygens in 1680 and Denis Papin in 1690 experimented unsuccessfully with similar devices. Robert Street obtained a patent in England in 1794 describing an internal-combustion engine employing a piston and a system of levers. In 1801 Philippe Lebon proposed in France that the charge be compressed before burning, but did not build an engine. W. Cecil experimented in England with an engine operated by exploding hydrogen-air mixtures and employing the vacuum acting on a piston as the products of combustion were cooled. Tests of this engine as reported in 1820 provide the first record of operation of a gas engine.

Actual production and sale of the gas engine began in 1823 when Samuel Brown started to build a vacuum-type gas-burning engine. The role of Brown in the development of the internal-combustion engine was similar to that of Thomas Newcomen in the steam-engine field. Their engines were heavy and crude but contained many essential elements of later more successful engines.

The most competent early study of the thermodynamic aspects of the internal-combustion engine was that of Sadi Carnot in France. He published a pamphlet in 1824 in which he outlined not only the fundamental internal-combustion engine theory, but even that of the diesel engine. Although he did not experiment with actual engines, his *Reflections on the Motive Power of Heat* undoubtedly influenced the thinking of many other experimenters.

One of the first engines to use pressure resulting from combustion rather than vacuum from cooling of the products was built by W. L. Wright in 1833. The first engine in which the charge was compressed before burning was built by William Barnett in 1838 and he was granted a patent which included this idea. He also built an engine of the two-stroke-cycle type with an external charging pump, an arrangement that was adopted many years later for diesel engines. The two-stroke cycle is completed in one up- and one downstroke of the piston or one turn of the crankshaft, in contrast with the four-stroke cycle that requires two full turns of the crankshaft. All such machines have operating cycles which, when repeated over and over again, periodically return all of their parts to their original positions.

Barnett also devised an ingenious igniting cock that provided a pilot flame for igniting the charge and a relighter to rekindle the pilot light after it was extinguished when the oxygen in the cylinder was consumed. This method of ignition was applied to many engines before electrical ignition was developed. Another method of ignition, the hot plug, was introduced by Alfred Drake in 1843.

Until 1860 few engines were built, and not many of those ever ran; but practical difficulties were gradually overcome and production facilities improved until it was possible to make a practical engine. In 1860 J. J. E. Lenoir, a Frenchman, marketed an engine that gave reasonably satisfactory service; it operated on illuminating gas. It was essentially a converted double-acting steam engine with slide valves to admit gas and air and to discharge exhaust products. It operated on a two-stroke cycle and, although it developed little power and utilized about 4% of the energy in the gas, several hundred were sold over a period of years.

In 1861 G. Schmidt proposed that the fresh charge be compressed by pumps to a pressure of three atmospheres before introduction to the cylinder. He stated that this would lead to a great expansion of the products of combustion and permit a greater transformation of heat energy. Schmidt was, therefore, one of the early proponents of the theory that compression should precede combustion, although his method of accomplishing the increase in pressure pointed toward the idea of supercharging rather than to the compression-type cycle.

The operating cycle of the modern automobile engine originated with Alphonse Beau de Rochas, who published his theory in Paris in 1862. He stated the conditions necessary for maximum economy as: (1) maximum cylinder volume with a minimum cooling surface; (2) maximum rapidity of expansion; (3) maximum ratio of expansion; and (4) maximum pressure of the ignited charge. He described the sequence of operations whereby this economy could be attained as: (1) suction during an entire outstroke of the piston; (2) compression during the following instroke; (3) ignition of the charge at dead centre and expansion during the next outstroke (the power stroke); and (4) forcing out the burned gases during the next instroke.

Although he never built an engine, Beau de Rochas's statement of factors affecting economy and performance appears as one of the most significant steps in the development of the internal-combustion engine. The four-stroke cycle he described is used in modern automobile engines. Because his work was entirely theoretical, Beau de Rochas has not been given the credit for originating the basic principle of the four-stroke-cycle engine; the name of Nikolaus Otto is commonly associated with that achievement.

The firm of Otto and Langen started production of a free-piston engine in Deutz, Ger., in 1867. Engines of this type had previously been built by Barsanti and Matteucci, but the Otto and Langen engine was superior in design and workmanship. It employed a vertical cylinder, open at the top and fitted with a heavy piston, below which was the combustion chamber. The gas and air charge was drawn into the cylinder during the first half of the upstroke. The charge was then ignited electrically and the piston lifted by the explosion. Although the piston tended to continue upward after the pressure on its underside had been reduced to a partial vacuum, atmospheric pressure acting on the top of the piston and the weight of the piston caused it to descend immediately. The motion was transmitted to a shaft and heavy flywheel by a toothed rack extending downward and meshing with a gear on the shaft. This gear turned freely on the shaft during the upward stroke, but a free-wheeling clutch engaged on the downward stroke and applied torque to the shaft. The engine was very noisy, of small power capacity and the rack-and-pinion mechanism unsound mechanically, but it consumed less than half as much fuel per unit of power as did the Lenoir engine and thus succeeded commercially.

In 1876 Otto and Langen applied the Beau de Rochas principle in the design of the Otto silent engine. This was the first four-stroke-cycle engine employing compression and operating on the principle of the modern automobile engine. In spite of its great weight and low economy, nearly 50,000 engines with a combined capacity of about 200,000 h.p. were reportedly sold in 17 years; this was followed by the rapid development of a wide variety of engines of the same type. Manufacture of the Otto engine in the United States began in 1878, following the granting of a U.S. patent to Otto in 1877.

The four-stroke cycle is illustrated in fig. 1. The piston first

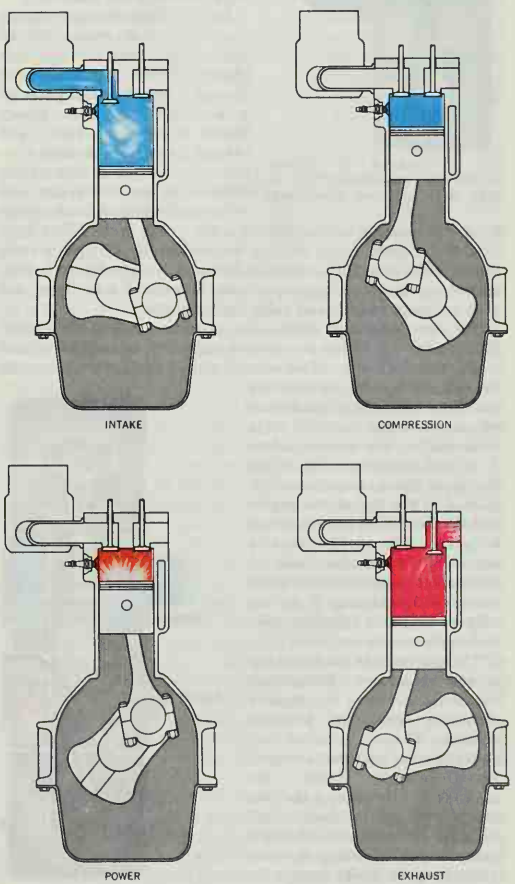

FIG. 1.—THE STROKES OF THE FOUR-STROKE CYCLE

descends on the intake stroke, during which the inlet valve is held open. The valves shown are of the commonly used poppet or mushroom type. The fresh charge is moved into the cylinder by the partial vacuum created by the descent of the piston. The piston then ascends on the compression stroke with both valves closed and the charge is ignited by an electric spark as the end of the stroke is approached. The power stroke follows, with both valves still closed and gas pressure acting on the piston crown because of the expansion of the burned charge. The exhaust stroke then completes the cycle with the ascending piston forcing the spent products of combustion past the exhaust valve, now held open by the valve train. The cycle then repeats itself. Each cycle thus requires four strokes of the piston—intake, compression, power and exhaust—and two revolutions of the crankshaft.

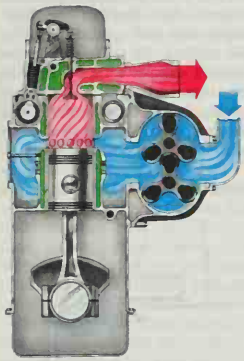

FIG. 2.—DIAGRAM OF BLOWER-SCAVENGED TWO-STROKE-CYCLE ENGINE WITH UNIFLOW SCAVENGING

The disadvantage of the four-stroke cycle is that only half as many power strokes are completed as in the two-stroke cycle and only half as much power would be expected from an engine of a given size at a given operating speed. The four-stroke cycle, however, provides more positive scavenging and charging of the cylinders with less loss of fresh charge to the exhaust.

Fig. 2 illustrates the modern two-stroke-cycle engine of the uniflow type, wherein the fresh charge is forced into the cylinder through circumferential ports by a positive-displacement rotary blower of the Roots type. The exhaust gases pass through poppet valves in the cylinder head, eliminating the return flow and reducing the loss of fresh charge by short circuiting to the exhaust outlet. The cycle differs from that of the simpler type only in the method of placing the fresh charge under pressure to cause its flow into the cylinder. All modern two-stroke diesel engines employ blowers of some type, but with a variety of port and valve combinations.

The opposed-piston engine also provides uniflow scavenging. This engine (fig. 3) has two pistons moving in opposite directions in the same cylinder. Two sets of ports extend entirely around the cylinder bore, so located that one set is covered and uncovered by one piston and the other set is controlled by the second piston. A second crankshaft, to which the upper pistons are attached, is located at the top of the engine and the two shafts are connected by gears. The effect is that of removing the cylinder heads of two similar engines, inverting one engine and attaching it to the other so that their cylinders unite to form a continuous bore.

The opposed-piston design has several advantages. Reciprocating masses move in opposite directions, providing excellent balance. The poppet valves, necessary in other uniflow-scavenged, two-stroke-cycle engines, are eliminated. By placing the two crankshafts several degrees out of phase (the one controlling the exhaust ports leading the one controlling the intake ports), the necessary blow-down period after the exhaust ports open can be provided before the inlet ports open. Intake of charge can continue after the exhaust ports are covered. The stroke of the engine is the combined movement of both pistons, and the combustion chamber formed between the two pistons at their innermost positions is desirably compact.

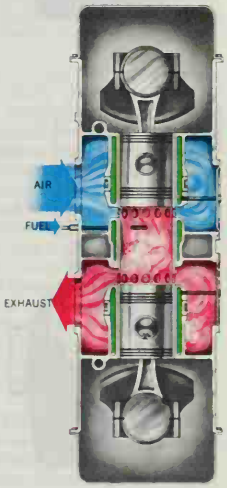

FIG. 3.—OPPOSED-PISTON ENGINE

Carburetor engines operating on the two-stroke cycle lack the fuel economy of four-stroke engines because some of the fuel escapes with the exhaust gases. This loss can be avoided in two-stroke spark-ignition engines only by equipping them with fuel-injection systems instead of carburetors and injecting the fuel directly into the cylinders after scavenging. Such an arrangement is attractive as a means of attaining high power output from a relatively small engine. Development of the turbocharger for this application held promise of further improvement.

Ignition of the charge by the high temperature attained by very high compression, hinted at by Carnot in 1824, became a practical reality in 1897 after five years of effort by Rudolf Diesel and his associates. The diesel engine (*q.v.*) differs from spark-ignition engines in that air alone is inducted into the cylinders, compressed to such an extent that a temperature exceeding the ignition requirement of the fuel is attained, and the fuel is injected into the combustion chamber where it burns. The carburetor and ignition system are eliminated, and improved economy results from the use of lower-grade fuels at higher compression ratios than are attainable with spark ignition.

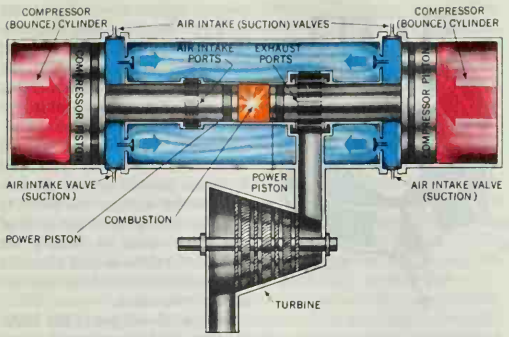
The Gas Turbine.—Continuous rotation is superior to reciprocating motion, and the imperfections of the reciprocating-piston engine are largely traceable to the noncontinuous motion and the cyclic interruption of combustion. The fundamental principle of the gas turbine was known before that of any other type of heat engine, historians having recorded that a toy gas turbine was built by Hero of Alexandria about the time of Christ. Nevertheless, practical development of the gas turbine did not take place until the 20th century. (*See* TURBINE: GAS.)

The gas turbine is a simple power plant. A compressor supplies air at about three to six times atmospheric pressure to a combustion chamber into which fuel is sprayed, maintaining continuous combustion. The resulting large volume of high-temperature gaseous products then expands through the turbine unit to atmospheric pressure. The compressor and turbine rotors may be on the same shaft. The excess of power developed in the turbine unit over that required to turn the compressor rotor is delivered to a generator, propeller or other load.

The Free-Piston Engine.—In the free-piston engine the pistons are not connected to a crankshaft, as in a conventional engine, but can transmit their power to a turbine instead. Originally built as an air compressor, the engine was first used extensively by the Germans in World War II for launching torpedoes.

The principle of the free-piston engine was known as early as 1857, but no practical engine of this type was built until 1867, when, as mentioned earlier, the German firm of Otto and Langen began production of its first internal-combustion engine. Early in the 20th century Hugo Junkers experimented in Germany with a free-piston apparatus. After World War I Raul de Pateros Pescara started work in France on a free-piston air compressor to serve as the power plant for a helicopter to be operated on the reaction-turbine principle. The application was soon abandoned, but work was continued on the compressor and an experimental unit was built in 1925. Junkers built his first practical free-piston compressor at about the same time. Pescara was granted patents on his ideas, and subsequent work on the free-piston engine was done by licensees under his patents. All early units were built as air compressors, and the possibilities of using the engine in combination with a gas turbine as a gasifier to replace the compressor and combustion chamber were not investigated until about 1937. The useful output of this combined free-piston engine and gas turbine is the power developed by the gas turbine.

The free-piston engine is a two-stroke-cycle opposed-piston engine in which each narrow power piston and its larger air-compressor piston move as a single unit. The combustion cylinder is horizontal and a larger compressor cylinder is located at each end. Diagrammatic sketches of the cylinder and piston arrange-



BY COURTESY OF GENERAL MOTORS CORP.

FIG. 4.—DIAGRAM OF A FREE-PISTON ENGINE

ment are shown in fig. 4. The power cylinder is surrounded by an annular air box that communicates with the two compression cylinders through spring-loaded automatic delivery valves and with the power cylinder through a set of intake ports around the circumference of the cylinder barrel. These intake ports are covered and uncovered by the piston at the left side of the engine in the figure. A second set of exhaust ports is controlled by the movement of the right piston and communicates with the exhaust-gas receiver. The exhaust turbine gets hot gases from this receiver. The pressure maintained in the receiver is usually 45 to 50 lb. per square inch (p.s.i.). Pressures up to 70 p.s.i. are more efficient, but create problems arising from higher temperatures.

The two compressor cylinders receive the air charge from the atmosphere through inwardly opening automatic intake valves, and maintain a high supercharging pressure in the air box. The outer faces of the compressor pistons are in contact with air trapped in the enclosed ends of the cylinder. This air acts as a cushion to bring the pistons to a stop as they are forced apart by the expansion of the combustion products in the power cylinder. The air pressure built up in these bounce cylinders acts to return the pistons after the products of combustion have left the cylinder through the exhaust ports and the fresh charge has been forced in through the intake ports by the pressure in the air box. The fuel injector at the centre delivers fuel to the combustion chamber formed between the two pistons.

The two double pistons are connected mechanically only by a synchronizing mechanism that keeps them in phase and is also used to move them to their outermost positions for starting the engine. The diesel principle functions in ignition. Starting is accomplished by admitting compressed air into the bounce cylinders and the air box from a storage tank. The air pressure on the bounce faces of the compressor pistons forces the pistons inward and compresses the air charge in the combustion chamber so that it attains ignition temperature, and the fuel is then sprayed in. The combustion builds up a high pressure between the two piston faces and forces them outward until their motion is arrested by the pressure in the bounce cylinders. The compressor cylinders are filled with fresh air through the automatic intake valves as the pistons are moved outward, and this air is delivered to the air box through the automatic delivery valves when the pistons are again moved inward by bounce-cylinder pressure.

The strokes of the two pistons are kept equal by the synchronizing mechanism, but the length of the strokes increases with the amount of fuel burned per cycle. At heavy loads the force acting on the faces of the power pistons is greater than at light loads, moving them farther apart and increasing the pressure in the bounce chambers. The greater returning force then pushes the pistons closer to each other at the inner ends of their strokes and thus increases the compression ratio. Higher compression ratios than are practical in conventional engines may be used because there are no bearings to be heavily loaded by the high pressure. The higher compression temperature permits fuels to be used that would not ignite satisfactorily in ordinary diesel engines.

Thus, the free-piston engine operates with a longer total stroke at heavy loads. In fact, there is a minimum load at which the engine can operate because the outward stroke must uncover the cylinder ports to permit exhaust of spent gases and recharge with fresh air. For large power capacity units this is not a problem because several gasifiers supply hot gases to one turbine and light loads are carried by shutting down some of the gasifiers. Twin-cylinder units will probably be commonest in such automotive applications as locomotives and tractors. Twin ("siamesed") gasifiers are controlled by a phasing linkage that keeps the two sets of pistons moving in opposite directions, thus reducing pulsations in the hot gas delivered to the turbine.

Free-piston gas-turbine units are used in electrical generators, ships, locomotives, pumps and compressors; these are units in excess of 1,000 h.p. Smaller units have been found practical in tractor operation. The cost of a free-piston power plant is about the same as that of a conventional diesel power plant and the thermal efficiency is only slightly higher. Perhaps its most attractive feature is its ability to burn a wider range of fuels than other engines. Compared with the conventional gas-turbine power plant, its efficiency is higher and the temperature of the gases leaving the free-piston gasifier is no higher than that at which some steam turbines operate. Blade erosion and other problems of high operating temperature of the gas turbine are thus minimized.

The NSU-Wankel Rotary-Piston Engine.—A rotary-piston internal-combustion engine developed in Germany is structurally so different from conventional reciprocating-piston engines that it has been claimed to be of revolutionary significance. The engine was conceived by Felix Wankel, a specialist in the design of sealing devices. Beginning in 1956, experimental engines were built and tested by the NSU Motorenwerke A. G. Neckarsulm, manufacturers of motorcycles and Prinz automobiles.

Instead of pistons that move up and down in cylinders, this engine has an equilateral triangular orbiting rotor that has the equivalent of three pistons in conventional engines. The rotor turns in a closed chamber and the three apexes of the rotor maintain a continuous sliding contact with the curved inner surface of the casing. Geometrically, the form of the casing is a two-lobed epitrochoid, an epicyclic curve formed by the path of a point on the radius of a circle as it rolls without sliding about the outside of a larger circle. The curved-sided rotor forms three crescent-shaped chambers between its sides and the curved wall of the casing. The volumes of the chambers vary with the rotor motion. Maximum volume is attained in each chamber when the side of the rotor forming it is parallel with the minor diameter of the casing, and the volume is reduced to a minimum when the rotor side is parallel with the major diameter. Shallow pockets recessed in the flanks of the rotor control the shape of the combustion chambers and establish the compression ratio of the engine.

In turning about its central axis, the rotor must follow a circular orbit about the geometric centre of the casing. The necessary orbiting rotation is attained through a central bore in the rotor in which an internal gear is fitted that meshes with a stationary pinion (with two-thirds as many teeth) fixed immovably to the centre of the casing. The rotor is guided by fitting its central bore to an eccentric formed on the output shaft that passes through the centre of the stationary pinion. This eccentric also harnesses the rotor to the shaft so that torque is applied when gas pressure is exerted against the rotor flanks as the fuel and air charges burn. The 3-to-2 gear ratio causes the output shaft to turn three times as fast as the rotor turns about the eccentric. Each quarter turn of the rotor completes an expansion or a compression, permitting intake, compression, expansion, and exhaust to be accomplished during one turn of the rotor. The only moving parts are the rotor and the output shaft.

The charge is supplied by a carburetor and enters the combustion chambers through an intake port in one of the end plates of the casing. An exhaust port is formed in one of the flattened sides of the casing wall and a spark plug is located in a pocket communicating with the chambers through a small throat in the opposite side of the casing wall.

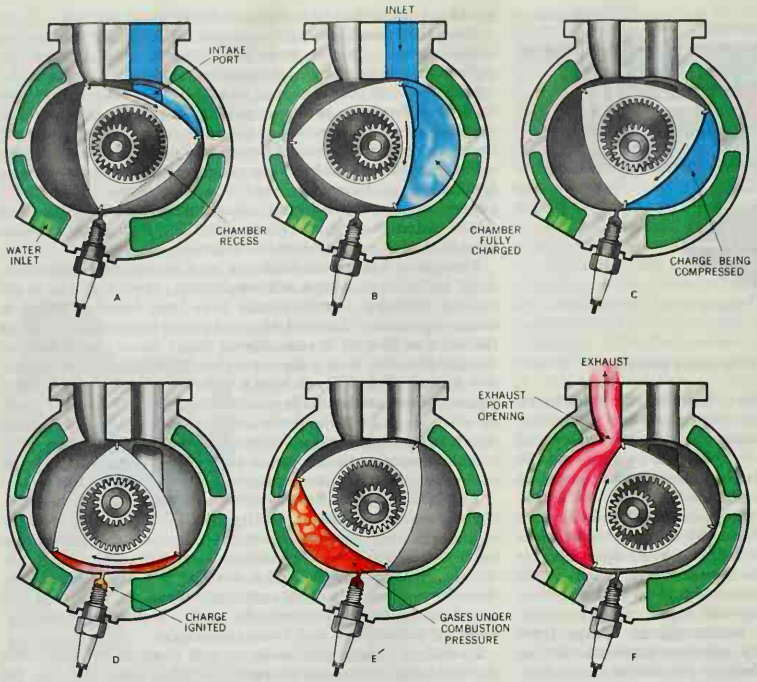


FIG. 5.—OPERATING PRINCIPLE OF NSU-WANKEL ROTARY ENGINE ILLUSTRATED BY FOLLOWING ONE SEGMENT OF THREE-SECTOR ROTOR (DESIGNATED BY HEAVY LINE) THROUGH COMPLETE CYCLE

(A) Intake begins (dotted lines indicate chamber recesses in rotor faces); (B) intake ends, chamber at maximum volume; (C) compression begins, chamber volume decreases; (D) chamber at minimum volume, charge fully compressed and ignited; (E) expanding gases produce clockwise thrust on rotor; (F) exhaust begins as rotor uncovers port

Referring to fig. 5, the cycle starts when the flank of the rotor (indicated by a heavy line in fig. 5[A]) is just uncovering the intake port, and the chamber formed between it and the curved casing wall is about to be cut off from the exhaust port by the adjacent rotor apex. Fig. 5(B) shows the rotor turned clockwise 60°, the crankshaft advanced a half turn, the crescent-shaped chamber at maximum volume, and the intake port about to be covered by the rotor. The charge is undergoing compression in fig. 5(C), and in fig. 5(D) it is fully compressed and is ignited by the spark plug. The expansion or power-producing period is under way in fig. 5(E) and is completed in fig. 5(F) as the shaft completes its second turn with the exhaust port partially uncovered by the rotor apex. An additional turn of the shaft is necessary to push the products of combustion out through the exhaust port, return the rotor to its initial position in fig. 5(A), and complete the cycle. Similar cycles are carried out simultaneously in the chambers adjacent to the other two rotor flanks, thus completing one power impulse for each turn of the shaft and making the unit equivalent to a single-cylinder two-stroke-cycle conventional engine.

The rotor and its gears and bearings are lubricated and cooled by circulating oil through the hollow rotor. The apex vanes are lubricated by a small amount of oil added to the fuel in proportions as low as 1 to 200. Water is circulated through cooling jackets in the casing, the entrance to which is located adjacent to the spark plug where the temperature tends to be highest.

Maintaining pressure-tight joints by suitable seals at the apexes and on the end faces of the rotor appears to be the major design problem. Radial sliding vanes are fitted in slots at the three apex edges and kept in contact with the casing by expander springs. The end faces of the rotor are sealed by arc-shaped segmental rings fitted in grooves close to the curved edges of the rotor and pressed against the casing by flat springs. Adjacent ring segments are fitted into recesses in a small cylindrical member at each end of the apex vanes. Each end is also slotted along one ordinate to receive the inner edge of the radial vane. The horseshoe-shaped outer ends of these six cylindrical plugs are pressed against the casing face by springs and serve to prevent leakage past the ends of the axial vanes by joining the ends of the three sealing elements that meet at each of the six corners of the rotor.

Major advantages of the NSU-Wankel engine are small space requirement and low weight per horsepower, smooth and vibrationless operation, quiet running and low-cost manufacture because of mechanical simplicity. Absence of inertial forces from reciprocating parts and elimination of spring-closed poppet valves permit operation at much higher speed than is practical for reciprocating-piston engines. This is fortunate because shaft speed must be high for optimum performance. Induction of fresh charge and exhaust are more effective because the ports are opened and closed more rapidly than are poppet valves, and gas flow through them is almost continuous. Heat transfer and the resulting cooling requirement are low because the jacketed surface is small. Fuel economy is claimed to be at least as good as that of conventional engines, providing knock-free combustion with a wider range of permissible fuels.

Engine Types.—A wide variety of internal-combustion engines resulted from the requirements of the extensive range of possible applications. Although these various engines differ radically in size, weight per unit of power developed, arrangement of components and details of operation, they are basically similar. The only exception is the gas turbine, which is fundamentally different from the piston engine. The only clearly defined separation into groups having similar design and operating characteristics is consequently the classification as piston types and gas turbines. Classification of reciprocating engines into sharply defined groups is difficult because of overlapping of characteristics.

The greatest differences among engines are those that arise in adapting the engines to various applications; *i.e.*, automotive, aviation, marine and stationary, with a wide range of special types included within each. Of these, the automotive is most important because of the number of engines in use and the total power developed. This group includes all engines used to propel land vehicles ranging from passenger automobiles to railway locomotives, with intermediate truck, tractor and bus types.

Perhaps the most striking of the differences between two types of engines are those that distinguish the locomotive diesel from the airplane engine. The most widely used locomotive diesel engine is a 16-cylinder V type engine weighing approximately 31,000 lb. and having a rating of 1,500 h.p. One of the best of the World War II airplane engines was also a 1,500-h.p. unit, a 12-cylinder V type engine weighing about 1,200 lb. The locomotive engine is two and one-half times as long as the airplane engine and weighs more than 25 times as much—a contrast that seems to indicate inefficiency in the locomotive engine. Such, however, is not the

case; both engines are of excellent design. The locomotive engine is a heavy-duty type designed for millions of miles of operation, much of the time at full throttle, and its crankshaft turns at less than one-third the speed of the airplane engine shaft, whereas the military aviation engine is designed for high specific output with a useful life of perhaps 700 hr.

The stationary power plant engine is usually even heavier than the locomotive type of the same cylinder dimensions and develops less power per unit of size and weight because of its durability and very low crankshaft speed. Falling between these two extreme types, aviation and stationary, are motor-vehicle engines of a wide variety, some of which are designed to operate at very high crankshaft speeds in order to reduce their size, cost and weight. It is evident that the important apparent differences among engines are largely traceable to the use for which they are intended.

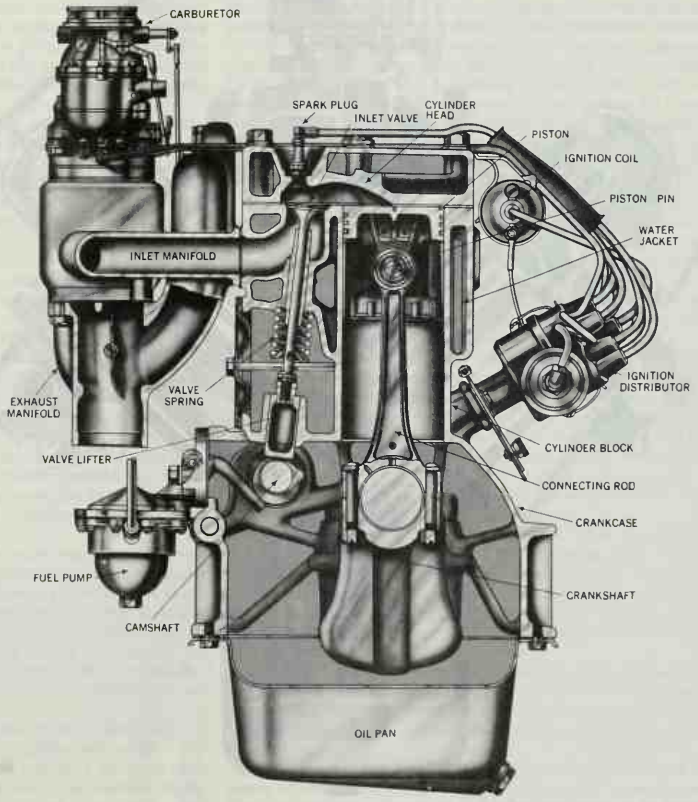
Differences in operation of engines also permit grouping certain types that have functional similarities. The most important differences result from: (1) whether the operating cycle is completed in two or four strokes of the piston; (2) whether the charge is ignited by an electric spark or by compression temperature; and (3) whether the fuel burned is gas, gasoline or fuel oil. Such differences are also superimposed on those that adapt the engines to their intended use, thereby multiplying the specification items necessary to define each type. For example, a stationary power plant engine may be a diesel or compression-ignition type, operating on the two-stroke cycle, and burning a heavy fuel oil, or it may be a spark-ignition engine, burning natural gas on the four-stroke cycle. These two engines appear to be very much alike because of the predominant effect of both being stationary power plant engines, but close examination reveals important mechanical and functional differences.

Engine Structure.—The following description of general engine construction is intended to indicate the essential components of an engine and to introduce and clarify the nomenclature of the various parts. The four-stroke-cycle automobile engine is used as the basic type. Fig. 6 shows a cross section of a typical cylinders-in-line automobile engine with the important parts indicated.

The main structural member of all automotive engines is the cylinder block, which usually extends upward from the centre line of the bearings that support the crankshaft to the junction with the cylinder heads. The block serves as the structural framework of the engine and carries the mounting pads by which the engine is supported in the chassis. Large stationary power plant engines and marine engines are built up from a foundation or bedplate and have upper and lower crankcases that are separate from the cylinder assemblies. The cylinder block of the automobile engine is an alloy casting with appropriate machined surfaces and threaded holes for attaching the cylinder head, main bearings, oil pan and other units. The crankcase is formed by the portion of the cylinder block below the cylinder bores and the stamped metal oil pan that forms the lower enclosure of the engine and also serves as the lubricating oil reservoir or sump.

The cylinders are openings of circular cross section that extend through the upper portion of the block with interior walls bored and honed to form smooth, accurate bearing surfaces. The cylinders of heavy-duty engines are usually fitted with removable liners made of metal more wear-resistant than that used in the block casting. Two arrangements of cylinders are in common automotive use—the vertical or in-line type and the V type. The in-line engine has a single row of cylinders extending vertically upward from the crankcase and aligned with the crankshaft main bearings. The V type has two rows of cylinders, usually forming an angle of 60° or 90° between the two banks. V-8 engines are usually of the 90° type. Fig. 7 shows a cross-sectional view of an automobile engine of the high-speed valve-in-head V-8 type. Large stationary-, marine- and locomotive-type engines with 12 cylinders commonly have 60° V's because of their firing interval, whereas 16-cylinder engines similarly have their cylinder banks at 45°. The conventional angle between the planes of the cylinder banks is 360° divided by half the total number of cylinders.

A passage is bored lengthwise in the block for the camshaft which operates the valves, and a gear or chain compartment for the camshaft drive from the crankshaft is formed between the front or rear end of the block and a cover plate. A bell housing is formed at the rear of the cylinder block to enclose the flywheel and provide for attachment of a transmission housing. Water jackets are formed around the cylinders with suitable cored connecting passages for circulation.



REPRINTED WITH PERMISSION FROM SOLBERG, CROMER AND SPALDING, "ELEMENTARY HEAT POWER," 1952, JOHN WILEY & SONS, INC.

FIG. 6.—CROSS SECTION OF L-HEAD AUTOMOBILE ENGINE

The design of the cylinder block is affected by the location of the valves of the four-stroke-cycle engine and by the provision of cylinder ports in the two-stroke-cycle type. The overhead-valve engine that largely replaced the L-head type has its valves entirely in the cylinder head, and no portion of the valve system is carried in the cylinder block except the camshaft and the cam followers or valve lifters that bear against the cams. The cylinder block of the L-head engine is extended to one side of the cylinder bores, as shown in fig. 6, with the valve seats and passages for inlet and exhaust, together with the valve guides, formed in this extension of the block. The cylinder head then becomes merely a water-jacketed cover, providing threaded locations for the spark plugs and with its underside so profiled that a combustion chamber of desired size and shape is formed above each cylinder bore. The depth of the combustion chamber in the L-head engine is increased above the valves and the space is thinned out above the piston at the side opposite the valves to permit control of combustion of the last portion of the charge to burn. The shape of the space forming the combustion chamber when the piston is at its closest approach to the cylinder head and the volume contained therein in relation to the piston displacement volume are extremely important in their effects upon performance. The cylinder head of the valve-in-head engine is narrower and deeper, and carries the valve seats, valve guides and valve ports.

The size of the combustion chamber relative to the volume displaced by the piston establishes the compression ratio of the engine. The piston displacement of a cylinder is the volume swept by the piston during one stroke and is equal to the cross-sectional area of the cylinder multiplied by the length of the stroke. The larger volume above the piston at the lowest point in its stroke divided by the combustion-chamber volume when the piston is at its highest point is the compression ratio of the engine. The larger volume is the sum of the piston-displacement volume and the combustion-chamber volume. The compression ratio may thus be expressed as the ratio of the sum of the piston-displacement volume and the combustion-chamber volume to the combustion-chamber volume. This ratio establishes the fraction of the original volume of the charge as inducted that the charge occupies at the end of the compression stroke and also the resulting compression pressure. Compression ratio is the most important factor affecting the theoretical efficiency of the engine cycle. Because increased compression ratio is the most basic way to improve efficiency, the automobile engine has tended toward higher compression ratios.

The pistons are cup-shaped cylindrical castings of steel or aluminum alloy. The upper, closed end, called the crown, forms the lower surface of the combustion chamber and receives the force applied by the combustion gases. The outer surface is machined to fit the cylinder bore closely and is grooved to receive piston rings that seal the gap between the piston and the cylinder wall. The rings are larger in diameter than the cylinders and gaps are provided so that they can be compressed into the bore. In the upper piston grooves are plain compression rings that prevent the combustion gases from blowing past the piston. The lower rings are vented to distribute and limit the amount of lubricant on the cylinder wall. Piston pin bosses are cast in opposite sides of the pistons and hardened steel pins fitted into these bosses pass through the upper ends of the connecting rods. The piston pins are frequently clamped in the eyes of the connecting rods, although floating pins (prevented by spring clips from contacting the cylinder walls) are sometimes used.

FIG. 7.—TRANSVERSE SECTION OF A V-8 ENGINE

A forged steel connecting rod of I section connects the piston to a throw (offset portion) of the crankshaft and converts the reciprocating motion of the piston to the rotating motion of the crank. The lower, larger end of the rod is bored to take a precision bearing insert lined with Babbitt or other bearing metal and closely fitted to the crankpin. V type engines usually have opposite cylinders staggered sufficiently to permit the two connecting rods that operate on each crank throw to be side by side. Some larger engines employ fork-and-blade rods with the rods in the same plane and cylinders exactly opposite each other.

Each connecting rod in an in-line engine or each pair of rods in a V type engine is attached to the throw of the crankshaft. Each

throw consists of a crankpin with a bearing surface, on which the connecting rod bearing insert is fitted, and two radial cheeks that connect it to the main journals that turn in the main bearings supported by the cylinder block. Sufficient throws are provided to serve all the cylinders, and the angles between them equal the angular firing intervals between the cylinders. The throws of a six-cylinder, four-stroke-cycle crankshaft are thus spaced 120° apart; those of an eight-cylinder engine are 90° apart because half of the cylinders fire in each turn of the crankshaft. The position of each throw along the shaft depends upon the firing order of the cylinders. Firing sequence is chosen to distribute the power impulses along the length of the engine to minimize vibration. Consideration is also given to the fluid flow pattern in the intake and exhaust manifolds. The standard firing order for a six-cylinder engine is 1–5–3–6–2–4, which illustrates the practice of alternating successive impulses between the front and rear halves of the engine whenever possible. Balancing is further improved by adding counterweights to the crankshaft to offset the eccentric masses of metal in the crank throws.

The crankshaft design also establishes the length of the piston stroke because the radial offset of each throw is equal to half the stroke imparted to the piston. The ratio of the piston stroke to the cylinder bore diameter is an important design consideration. No logical basis for the establishment of this ratio existed in the early years of engine development and a range from unity to one and one-half was used by the different manufacturers. As engine speeds increased, however, and it became apparent that friction horsepower increased with piston speed rather than with crankshaft rotating speed, a trend toward short-stroke engines started. Strokes were shortened to as much as 20% less than the bores.

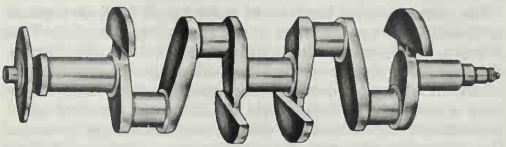
Other advantages are gained by short strokes, such as providing more cylinder-head surface for valves in proportion to piston displacement and decreasing the height of the engine. Engines with low stroke-bore ratios have slightly greater horsepower, principally because of reduced friction losses.

The arrangement of the throws of the crankshaft for a multicylinder four-stroke-cycle engine is chosen with regard to the firing order of the cylinders and the angular interval between firing impulses. The average number of degrees through which the crankshaft must turn between successive firings is found by dividing 720° (the two turns completed by the crankshaft during a complete cycle) by the number of cylinders. A two-cylinder, four-stroke-cycle engine thus fires at 360° intervals and the second piston must arrive at top dead centre exactly one full turn after the first piston. If the two cylinders are in line, the two throws of the crankshaft must be 360° apart. They will then lie in the same plane with their crankpins exactly in alignment and the two pistons will move up and down in unison. This is just the opposite of the requirement for mechanical balance that one piston rise as the other descends. If that plan were followed, however, the two pistons would arrive at their dead centre points 180° apart and consequently be in firing position 180° apart on the same turn of the crankshaft. The firing intervals would then be 180° and 540° instead of uniformly 360°, and both cylinders would fire during one crankshaft turn with neither firing during the next turn. Under these conditions torque would not be uniform and the engine would not run smoothly.

From the requirements for the two-cylinder engine a general rule for the layout of the throws of four-stroke-cycle multicylinder crankshafts can be expressed. Regardless of the number of cylinders, two pistons must arrive at top dead centre in unison so that a second cylinder is ready to fire exactly 360° after each cylinder fires. Half of the cylinders then will fire during each turn of the crankshaft. To follow this rule, there must be an even number of cylinders in order that there may be pairs of cylinders whose pistons move in unison.

An eight-cylinder engine fires each time its crankshaft makes a quarter turn if the intervals between impulses are equal. The crankshaft for an eight-cylinder in-line engine is designed with each of its eight throws a quarter turn away from another throw. All of the throws then lie in two planes that intersect at right angles. A V-8 engine must have its banks 90° apart so that two pistons can arrive at top dead centre at each quarter turn of the crankshaft.

For best lengthwise balance, the cylinders whose pistons are in phase are the first and last cylinders of an in-line engine, the second and next to the last, continuing in that order with crank throws that are in alignment equidistant from the centre of the engine. This is illustrated in the four-cylinder crankshaft of fig. 8.



BY COURTESY OF GENERAL MOTORS CORP.

FIG. 8.—CRANKSHAFT FOR A FOUR-CYLINDER ENGINE

With two pistons reaching their uppermost positions simultaneously, there are two possible firing orders in the four-cylinder in-line engine, four in the six-cylinder engine, and eight in the eight-cylinder engine. The final choice is based on the distribution of the impulses along the length of the engine, which affects intake manifold functioning and the lengthwise rocking tendency of the engine. The firing order selected is then established by designing the camshaft so that the inlet and exhaust valves open in the selected sequence.

Cylinder Charging.—All internal-combustion engines convert heat into mechanical energy or power. First the combustible charge is introduced. One hundred or more cubic feet of air must be pumped into an engine per hour for each horsepower developed in order to supply the oxygen needed for combustion. The engine must function as an air pump as the first step in its operation. Cylinder charging includes ridding the cylinder of the spent products of combustion of the previous cycle to make room for the next charge. This is done by direct pumping on the exhaust stroke of the four-stroke-cycle engine or by pushing out the exhaust gases ahead of the fresh-air charge pumped in by the scavenging pump or blower of the two-stroke-cycle engine.

Pumping in the four-stroke engine involves an exhaust valve held open during the upward stroke that follows the power stroke and an inlet valve that is held open during the next downstroke. The valves remain open for longer periods than the corresponding piston strokes to provide time for opening and closing, and to utilize the inertia effects of the high velocity at which the gases flow. The opening and closing points of both valves are therefore displaced somewhat from dead centre.

The exhaust valve is timed to open at approximately 50° before the piston reaches its bottom dead centre on the power stroke. This occurs well before the power stroke is completed in order to provide a blow-down period to release the gases from the cylinder and reduce the pressure approximately to exhaust-manifold pressure by the end of the power stroke. Some useful work near the end of the power stroke is lost by this early valve opening, but additional negative work during exhaust is avoided by not requiring the piston to ascend against back pressure.

The exhaust valve remains open about 15° after top dead centre, allowing the kinetic energy of the outflowing gases to reduce the pressure within the combustion chamber below atmospheric pressure and decrease the exhaust gases remaining to dilute the next charge. The partial vacuum created is also useful in permitting the inlet valve to be opened early and the flow of fresh charge into the cylinder to be started sooner.

The inlet valve opens about 15° before top dead centre to take advantage of the pulling effect at the end of the exhaust period. About 30° of overlap results from the advanced inlet opening and delayed exhaust closure. The overlap period helps scavenge the chamber.

The inlet valve is not closed until 50° or more after bottom dead centre to utilize the kinetic energy of the rapidly moving charge. The optimum inlet closure point depends upon the speed at which the engine is to operate, low-speed engines having much earlier

closure than high-speed types. The greater the departure of all valve events from the dead centre points, the higher the speed at which the power of the engine will reach its peak. So-called racing cams are designed with all opening events earlier than normal and all closing events, especially inlet closure, later than in conventional timing. This causes the engine to develop higher maximum power at a higher speed, but low-speed performance is impaired.

The extent to which the cylinder is filled with fresh air depends upon such factors as the speed of the engine, the size of the flow passages, valve size, amount of lift and timing. The effectiveness of the charging process of the four-stroke engine is expressed as volumetric efficiency, defined as the weight of fresh air inducted per cycle as compared with the weight required to fill a volume equal to the piston displacement at outside temperature and pressure. The volumetric efficiency of an automotive engine usually rises to a peak of slightly more than 80% at about half the rated speed of the engine and then decreases considerably at higher speed. This change in air charge per cycle with engine speed is reflected in proportionate changes in the torque or turning effort applied to the crankshaft and causes the power the engine can deliver at full throttle to reach a maximum as engine speed increases. At speeds above this peaking speed the air charge inducted per cycle falls off so rapidly that less power is developed than at lower speeds. The inability of the engine to induct a full charge of fresh air at high speeds limits the power output of the engine.

Supercharging is employed to permit the engine to maintain its charging effectiveness at high crankshaft speeds and at high altitudes. Supercharged engines differ from conventional engines in that a pump or blower is provided to raise the pressure of the air supplied to the cylinders, increasing the weight of charge. The approximately 50% loss in power suffered by unsupercharged engines at 20,000 ft. altitude can be largely restored; it is also possible to more than double the power of an engine by supercharging.

Supercharging is more applicable to compression-ignition engines than to spark-ignition types. Increased charge density and temperature, resulting from supercharge, increase the tendency for combustion knock or roughness in the spark-ignition engine and necessitate an undesirable decrease in compression ratio or the use of a fuel of higher antiknock quality. The diesel engine, however, benefits from supercharging because of improved ignition. Four-stroke-cycle diesel engines are commonly supercharged to improve their competitive position with the two-stroke diesel and spark-ignition engines.

The supercharging blower may be geared to the crankshaft, in which case the power consumed in driving it is added to the friction loss of the engine. The turbocharger employs a gas turbine operated by the exhaust gases to drive a centrifugal blower. The turbocharged engine not only gains increased power capacity, but also operates at improved fuel economy. Turbochargers are used extensively to supercharge the larger four-stroke cycle engines and have found some application on two-stroke-cycle diesel engines. Airplane engines are usually supercharged both by geared blowers and by turbochargers to provide the large pumping capacity needed at high altitude.

Performance.—The performance of an engine is expressed in terms of power, speed and fuel economy. The three quantities are evaluated with a dynamometer, a laboratory device that applies a controllable load in the form of resistance to the turning of the crankshaft, and also measures the torque exerted at the shaft coupling. The resistance imposed by the dynamometer may be so adjusted that the desired engine speed is established at any throttle position. It is thus possible to run the engine at various speeds throughout its operating range, to maintain these operating conditions continuously and to measure the precise loads and speeds at which each run is made. Additional test equipment permits measurement of the exact quantity of fuel consumed as well as the duration of the runs. Certain types of dynamometers also make it possible to determine the amount of power consumed by frictional and other losses in the engine. From these data the power-speed-economy relationships can be calculated, performance plotted and much information regarding the suitability of the engine for its purpose derived. More thorough tests are sometimes conducted to determine the durability of the engine, quietness and smoothness of operation, accelerating ability, cooling requirements, fuel limitations, air consumption, etc.

The power produced by an engine is expressed in horsepower, a unit established by James Watt in rating his steam engines. He tested several horses to determine the rate at which they could work and decided that 33,000 foot-pounds (ft.-lb.) per minute was a liberal unit, representing appreciably more work than an ordinary horse could do for a short time. A foot-pound is equivalent to lifting a mass of one pound a distance of one foot. A horsepower therefore represents the work done in one minute by some force (in pounds) acting through some distance (in feet) such that the product is 33,000.

When the power developed is measured by means of a dynamometer or similar braking device, it is called brake horsepower or shaft horsepower. This is the power actually delivered by the engine and is therefore the capacity of the engine. Engineers are also interested in the power developed in the combustion chamber of the engine, which is greater than the delivered power because of friction and other mechanical losses. This power loss, called the friction horsepower, can be evaluated by "motoring" the engine with a suitable dynamometer when no fuel is being burned. The power developed in the cylinders can then be found by adding the friction horsepower to the brake horsepower. This quantity is the indicated horsepower of the engine, so called from an instrument known as the engine indicator, used to measure the pressure on the pistons and thus calculate the power developed in the cylinders. The engine indicator traces curves of pressures acting on the piston versus volume changes in the cylinder caused by piston motion during the strokes that correspond to one cycle.

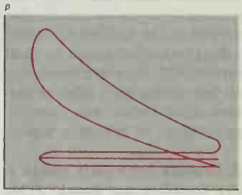
Fig. 9 shows a pressure-volume diagram for an internal-combustion engine. From this diagram it is possible to evaluate the average pressure which, if it acted constantly on the piston for one stroke, would produce a motivating force equal to that produced by the varying pressure during an entire cycle. It is thus possible to find the net force in pounds that would act on the piston during one power stroke if this average pressure is expressed in pounds per square inch and multiplied by the area of the piston in square inches. This pressure is called the mean effective pressure (m.e.p.) of the cylinder and is defined as the constant pressure that would do the same amount of work as the varying pressure in the entire cycle. This quantity can be used to calculate the power developed in the cylinder by substituting in the equation

$$\text{indicated horsepower} = \frac{PLAN}{33{,}000}$$

where P is the mean effective pressure in pounds per square inch, L is the length of the stroke in feet, A is the piston area in square inches and N is the number of cycles completed per minute.

Friction horsepower is caused for the most part by friction between cylinder walls and pistons and by the work done in pumping the charge into and out of the cylinders. In addition to these large mechanical losses, smaller amounts of power are spent in operating the valves, driving the cooling fan, generator, ignition system, and the oil and coolant pumps.

Mechanical efficiency is defined as brake horsepower in per cent of indicated horsepower. Friction horsepower increases rapidly with increased piston speed, but is fairly independent of load. The mechanical efficiency of an engine, therefore, increases with load at constant speed but decreases with increased speed at constant throttle and is usually between 70% and 90% within the normal operating speed range.



BY COURTESY OF O. C. CROMER

FIG. 9.—ENGINE INDICATOR DIAGRAM FOR FOUR-STROKE-CYCLE INTERNAL-COMBUSTION ENGINE (*see* TEXT FOR FURTHER INFORMATION)

A quantity called brake mean effective pressure (b.m.e.p.) is obtained by multiplying the mean effective pressure of an engine

by its mechanical efficiency. This is a commonly used index expressing the ability of the engine, per unit of cylinder bore, to develop useful pressure in the cylinders and deliver power. If the power delivered is increased by any change other than an increase in speed or cylinder dimensions, its b.m.e.p. increases proportionately. The b.m.e.p. reflects any improvement in power output and permits a comparison of effectiveness of engines differing in size that cannot be made from their power outputs alone.

Horsepower is calculated by measuring the torque applied to the dynamometer in restraining the rotation of the crankshaft. Torque is equal to the product of a force and the perpendicular distance from the centre of rotation to the line of action of the force. Torque may be expressed in units of pound-feet, and careful distinction must be made between this unit and the foot-pound used in measuring work. Work may or may not be done by the application of torque. If the torque is insufficient to overcome resistance to turning, then no work is done, but, if the torque causes rotation, work done per turn equals the product of the force acting and the circumstance of the circle to which the force is tangent.

Dynamometer data include the length of the dynamometer arm, which is the torque arm or radius R (in feet) of the torque circle, the reaction of the scales W (in pounds) which is the force acting, and the number of turns n made by the crankshaft of the engine per minute. By Watt's definition, brake horsepower may be calculated as follows:

$$\text{brake horsepower} = \frac{2\pi RWn}{33{,}000}$$

This equation may be simplified by dividing the denominator by 2π and substituting torque, t, for RW, which results in the equation

$$\text{brake horsepower} = \frac{tn}{5{,}252}$$

The brake mean effective pressure may be calculated from the dimensions of the engine and the brake horsepower as determined from dynamometer data. The equation, indicated horsepower = $PLAN/33{,}000$ may be converted to brake horsepower by substituting b.m.e.p. for indicated mean effective pressure. This substitution is possible because b.m.e.p. bears the same relationship to m.e.p. as brake horsepower does to indicated horsepower. If b.m.e.p. is expressed by P_b, the equation becomes

$$\text{brake horsepower} = \frac{P_bLAN}{33{,}000}$$

The power determined by a test of an automobile engine is affected by such test conditions as atmospheric pressure, temperature and humidity, exhaust back pressure, and the number of accessories attached to the engine. Automobile manufacturers in the U.S. adopted a standard code of rating tests for establishing the advertised horsepower of their engines. The conditions specified by this code are favourable to the engine and yield higher horsepower ratings than would be developed in normal operation. This practice establishes another, slightly smaller horsepower unit for engine-rating purposes. In 1906 the Royal Automobile club in Great Britain adopted an approximate horsepower rating based upon an assumed piston speed of 1,000 ft. per minute and a b.m.e.p. of 67 lb. per square inch. The rating is expressed by the equation

$$\text{horsepower} = \frac{B^2N}{2.5}$$

where B is the cylinder bore in inches and N is the number of cylinders. The same formula was adopted in the U.S. by the Association of Licensed Automobile Manufacturers and became known as the ALAM rating. Piston speeds and brake mean effective pressures of modern engines are much higher than assumed in the formula, and it is not unusual for the manufacturer's rating to exceed the horsepower calculated by this formula by a factor as large as five. This formula is widely used as a basis for licences and taxes.

The horsepower unit in Europe, where the metric system is used, is slightly smaller than Watt's unit. It evaluates a horsepower as work done at the rate of 4,500 kilogram-metres per minute and is 98.6% as large as the English and U.S. unit.

To compare engines of differing size, it is customary to divide the horsepower by the piston displacement, arriving at the power per unit of cylinder size. Either the engine speed or m.e.p. must be increased to increase the power per cubic inch of piston displacement. Because it is difficult to maintain effective cylinder charging and low friction losses at high speed, high specific power output as expressed by this unit represents a desirable design achievement. The usual range is from $\frac{1}{2}$ to $\frac{7}{8}$ of a horsepower per cubic inch of displacement for automobile engines and much less for slow-speed engines. Some high-performance automobile engines are available that operate at very high speed and are rated at slightly more than one horsepower per cubic inch. Supercharged engines develop considerably more than this.

The fuel economy of an engine is expressed in pounds of fuel per brake horsepower per hour. This quantity is found by weighing the fuel burned during a test run at constant operating conditions, converting the weight to pounds per hour and dividing by the brake horsepower developed during the test. The rate of fuel consumption evaluated by this unit is called the brake specific fuel consumption (b.s.f.c.). The fuel economy of an automobile engine is usually best at about half its rated speed and at three-quarters or more load.

Performance curves are drawn for a variable-speed engine by plotting power and economy against engine revolutions per minute. Fig. 10 is a set of such performance curves for a typical automobile engine. These curves show that both the torque and the b.m.e.p. curves follow the changes in cylinder-charging effectiveness reflected in the volumetric efficiency curve. The brake horsepower curve is also seen to reach a peak at the speed above which the torque and b.m.e.p. are decreasing more rapidly than the speed is increasing.

Theoretical Cycles.—Improvements in engine performance were brought about by studying and analyzing the results of tests.

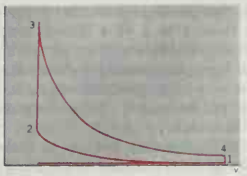
FIG. 10.—PERFORMANCE CURVES FOR TYPICAL AUTOMOBILE ENGINE

The engine indicator diagram permits theoretical analysis when simplified by substituting conventional standard processes of thermodynamics for its irregular and unsystematic curves. The indicator diagram of fig. 9 then appears as a summation of four processes as shown in fig. 11, the diagram of the ideal Otto cycle.



BY COURTESY OF O. C. CROMER

FIG. 11.—THEORETICAL OTTO-CYCLE PRESSURE-VOLUME DIAGRAM (*see* TEXT FOR FURTHER INFORMATION)

The lower loop of the indicator diagram that reflects the intake and exhaust strokes is eliminated by the assumption that these strokes are carried out at atmospheric pressure. Further simplifying assumptions are that air is the working fluid throughout the cycle and its properties are those of atmospheric air. The cycle then starts with atmospheric conditions at the point 1. The processes 1–2 and 3–4 both follow the theoretical paths for isentropic compression and expansion resulting from the assumption that no heat is transferred to or from the working fluid. The pressure at each point along these curves is established by the perfect gas relationship pv^K = a constant, wherein p is the absolute pressure of the air, v is the volume occupied by a unit mass of air and K is the ratio of the specific heat at constant pressure to that at constant volume, which may be taken as 1.4 for atmospheric air. The processes 2–3 and 4–1 are carried out at constant volume, since it is assumed that energy is gained by combustion from 2 to 3 instantaneously and that rejection of energy to the exhaust from 4 to 1 is also instantaneous.

The theoretical or ideal Otto cycle may be analyzed by evaluating the energy quantities in the equation for efficiency, η:

$$\eta = \frac{\text{net work}}{\text{energy supplied}} = \frac{Q_{\text{in}} - Q_{\text{out}}}{Q_{\text{in}}} = \frac{Q_{2-3} - Q_{4-1}}{Q_{2-3}}$$

Thermodynamic relationships permit the evaluation of Q (quantity of heat) between 2 and 3 in terms of specific heat and the temperatures at the two points, and similarly for Q between 4 and 1. An expression in terms of the temperatures at the four corners of the indicator diagram is thus obtained. Further application of thermodynamics yields a simpler and more useful expresssion in terms of the maximum and minimum volumes of the cycle

$$\eta = 1 - \frac{1}{(V_1/V_2)^{K-1}}$$

The ratio V_1/V_2 is the compression ratio of the cycle or engine. Substituting r, the compression ratio, for V_1/V_2 gives the theoretical efficiency equation

$$\eta = 1 - \frac{1}{r^{K-1}}$$

The theoretical Otto-cycle efficiency is the thermal efficiency of the cycle and is equivalent to the fraction of the energy supplied that is converted into work. No losses other than those inherent in the cycle are involved and only a perfect engine operating on that cycle could attain such high efficiency. The practical losses include failure to burn the fuel completely and to duplicate the cycle processes exactly, the heat transferred from the engine, the friction losses and so on. The thermal efficiency of the actual engine is calculated from test data and is much lower than the theoretical efficiency, perhaps only half as large.

The brake thermal efficiency of an engine is the fraction of the energy supplied in the fuel that is available as brake horsepower. The heating value of the fuel must be known to evaluate the energy supplied. Fuel is tested for heating value in a calorimeter that transfers the heat released by burning a known weight of the fuel to a known weight of water. The amount of heat required to raise one pound of water 1° F. is called a British thermal unit (B.T.U.). The number of British thermal units released by the combustion of a pound of fuel is its heating value Q_H. For gasoline this value is about 20,000 B.T.U. per pound. The power developed by the engine can also be expressed in British thermal units because 1 B.T.U. is equivalent to 778 ft.-lb. of work. One horsepower delivered continuously for one hour is thus equivalent to 2,545 B.T.U. Since brake specific fuel consumption is the pounds of fuel burned in one hour to deliver one horsepower, brake thermal efficiency may be expressed as

$$\text{brake thermal efficiency} = \frac{2{,}545}{\text{b.s.f.c.} \times Q_H}$$

The curves of fig. 12 show the theoretical Otto-cycle efficiency and the approximate brake thermal efficiency of an engine operating on the Otto cycle for compression ratios from 2 to 20. The approximate ranges of the compression ratios of spark-ignition engines and diesel engines are also indicated. The upper portion of the spark-ignition engine range is attainable only by engines operating with natural gas or extreme high-octane fuels.

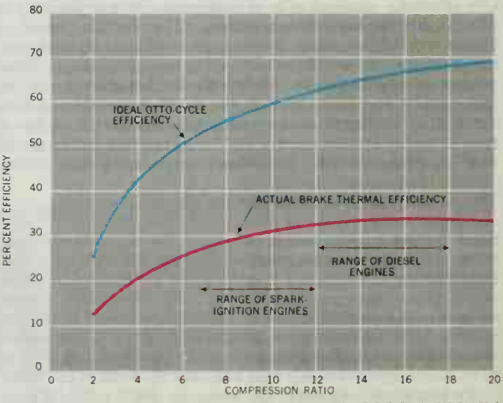
The cycle described by Diesel in his 1893 patent differs from the Otto cycle only in that energy is supplied more slowly, at a rate such that the increase in volume during combustion exactly compensates for the tendency of the pressure to rise. Energy is thus supplied at constant pressure instead of at constant volume as in the Otto cycle. Combustion in an engine following this cycle occurs more gradually during the early part of the power stroke instead of instantaneously at the dead centre point, and the path 2–3 (fig. 11) is horizontal instead of vertical. The efficiency of the Diesel cycle is usually expressed as

$$\eta = 1 - \frac{1}{r^{K-1}}\left[\frac{r_c^K - 1}{K\,(r_c - 1)}\right]$$

where r_c is the cutoff ratio or ratio of expansion during combustion V_3/V_2. The value of the bracketed factor exceeds unity for any practical cutoff ratio and the subtractive term is consequently greater than that of the Otto-cycle expression, $1/(r^{K-1})$. The efficiency of the Diesel cycle is thus lower than that of the Otto cycle for the same compression ratio by an amount that increases with the energy input. An engine operating on this cycle would then be more efficient at a light load than at a heavier load.

The value of K in theoretical efficiency expressions is higher for air than for fuel vapours. It can be shown by calculating K for various air-fuel ratios that the efficiencies of Otto and Diesel cycles are higher when air is considered as the working fluid and become lower as fuel is included in the charge. It is evident that lean mixtures are theoretically more efficient than those containing more fuel.

However, combustion in the spark-ignition engine is slowed down as the mixture is leaned beyond the maximum-economy ratio, causing combustion to depart from the constant-volume Otto cycle and tend toward the less efficient constant-pressure Diesel cycle. On



REPRINTED WITH PERMISSION FROM SOLBERG, CROMER AND SPALDING, "ELEMENTARY HEAT POWER," 1952, JOHN WILEY & SONS, INC.

FIG. 12.—CURVES SHOWING EFFECT OF COMPRESSION RATIO ON THEORETICAL OTTO-CYCLE EFFICIENCY AND APPROXIMATE BRAKE THERMAL EFFICIENCY

the other hand, the compression-ignition engine is inherently a lean-mixture engine, and its combustion is not retarded by excess air. The higher efficiency of the diesel engine arises from its higher compression ratio and its higher air-fuel ratio. High-speed diesel engines follow the Otto cycle.

These theoretical analyses indicate three factors affecting efficiency. First, the compression ratio should be as high as is practical; second, combustion should be as rapid as is practical; and third, the air-fuel ratio should be high. These criteria favour the principle of compression ignition because the compression ratio is not limited by knocking and preignition as it is in the spark-ignition engine, and high air-fuel ratios will not impair combustion. As shown by the curves of fig. 12, the important gains in efficiency from increased compression ratio were made when ratios were increased from about 4 to 7; further increases above 12 result in proportionately less theoretical improvement and very little actual gain in thermal efficiency.

Charge Requirements.—The amount of oxygen necessary to support the combustion of fuel may be readily calculated if the chemical ingredients are known. It is customary to assume that gasoline is a mixture of many hydrocarbons that average approximately the same as octane, C_8H_{18}. With this assumption it is possible to write the combining equation for gasoline and air as

$$C_8H_{18} + 12.5\ O_2 + 47.5\ N_2 \rightarrow 8\ CO_2 + 9\ H_2O + 47.5\ N_2$$

For one pound of fuel, the equation reads

$$1\text{ lb. } C_8H_{18} + 3.51\text{ lb. } O_2 + 11.66\text{ lb. } N_2 \rightarrow 3.09\text{ lb. } CO_2 + 1.42\text{ lb. } H_2O + 11.66\ N_2$$

or

$$1\text{ lb. } C_8H_{18} + 15.17\text{ lb. air} \rightarrow 16.17\text{ lb. products of combustion}$$

These equations represent the proportion for complete combustion. The imperfections of the combustion chamber, incomplete mixing of the fuel and air, insufficient time for the reaction to go to completion and other unfavourable factors prevent perfect combustion.

Empirically, a slightly lean mixture, about 16 to 1, is more economical than the 15.17 to 1 ratio shown in the equation above. The excess air helps complete combustion, but less power is developed because a smaller amount of fuel is contained in the leaner mixture. Further leaning of the mixture is uneconomical because the burning rate of the charge is decreased. A somewhat rich mixture, about 12 to 1, yields more power than the theoretical chemical ratio. This is because the additional fuel introduces more chemical energy to the combustion chamber and, although combustion is slightly less complete, the net energy release is increased. Further enrichment reduces the power output by decreasing the burning rate.

Combustion.—In the spark-ignition engine the high temperature of the electric spark ignites the tiny portion of the charge in the immediate vicinity of the spark-plug gap. This first presents a somewhat spherical surface of flame to the surrounding layer of charge, causing it to ignite and expose the next layer to an igniting flame. As the charge is exposed to this flame front, layer by layer, the sphere grows until it spans the combustion chamber. The flame front then advances radially across the chamber and, if undisturbed, progressively burns the remainder of the charge. Normal combustion, then, depends on the density of the charge, the speed at which the flame front advances and the area of the flame surface. Although the entire process is completed in a fraction of a second, there is no instant during the process when any sizable portion of the charge is burning. Energy is thus released uniformly and without violence.

As each portion of the charge burns, the volume of space occupied by the products increases. This expansion of the burned portion of the charge compresses the unburned portion into a smaller volume than it originally occupied. A compression of this sort is accompanied by an increase in temperature. The temperature and density attained by the last portion of the charge may be so great that the entire remaining charge will self-ignite with explosive violence. Such almost instantaneous combustion sets up a high-frequency pressure wave within the gases. The resulting vibration of the chamber walls produces an audible knock. When knocking occurs, the engine is noisy and the temperature of the combustion chamber rises rapidly, accompanied by a loss in power. Only the last portion of the charge, that farthest from the spark plug, is involved in this irregularity, and knocking will not occur if the fuel can resist self-ignition until it is burned in the normal manner by the arrival of the flame front. This phenomenon is called normal knock and can be avoided by using fuel resistant to self-ignition or by improvements in combustion-chamber design.

Fuels.—To suit the needs of a modern engine a gasoline must have the volatility for which the fuel system of the engine was designed, and antiknock quality, as indicated by its octane number, sufficient to avoid knock under normal operation. Other specifications must also be met, but volatility and octane number are the most important. Starting quality, vapour-locking tendency, rapidity of warm-up, acceleration, crankcase dilution, power and completeness of combustion are some of the performance factors affected by volatility. The octane number of a gasoline determines whether knock-free operation is possible in a given engine. The size and structural arrangement of the molecules principally determine the octane number of a gasoline.

Large straight-chain molecules react most readily, whereas small compact molecules are most resistant to chemical reactions. The size of the molecules and, to a lesser extent, their structure also affect the volatility of the fuel. The smallest hydrocarbon molecule, that of methane, has the lowest boiling point, −259° F., and it is so volatile that it exists as a gas at atmospheric conditions. It is also resistant to self-ignition and therefore has high antiknock quality. Cetane is an example of the opposite extreme. It has a long straight chain with 16 carbon atoms, reacts with oxygen at relatively low temperature and boils at 536° F. Intermediate compounds, of which gasoline is composed, have molecules with from 5 to 12 carbon atoms and a boiling point range from about 100° to 400° F.; the molecules are largely of branched-chain and ring structure that vary considerably in chemical activity.

The octane-number rating of gasoline is based on its knocking tendency and the effect of increased compression ratio on the knocking tendency of an engine. A special single-cylinder test engine with adjustable compression ratio is used to compare the knock intensity of the gasoline under test with that of blends of two reference fuels.

Iso-octane, a branched-chain hydrocarbon of high antiknock quality, is blended with normal heptane, a straight-chain hydrocarbon that knocks severely, in varying proportions by volume. The engine is operated on the gasoline and the compression ratio adjusted until a knock of a standard intensity, as established by the test code, is indicated by a knock meter. Reference blends of octane and heptane are then successively substituted for the gasoline at the same compression ratio until the same knock intensity is again indicated. The per cent of octane in the reference blend that causes the same knock intensity is the octane number of the gasoline.

A 100-octane fuel has the same knocking tendency as iso-octane and one that behaves the same as normal heptane is a 0-octane fuel. An 80-octane fuel has the same antiknock quality as a mixture of 80% iso-octane and 20% normal heptane. It should be noted that no quality other than knocking tendency is indicated by octane number.

The petroleum chemists have devised refining techniques whereby molecules of compact structure and desirable antiknock characteristics are produced in much larger amounts from crude oil. Additives, principally tetraethyl lead, also contribute to knock resistance.

For many years gasoline and other volatile portions of crude oil were thrown away for want of a market, but the advent of the automobile made it desirable to increase the yield of gasoline. Only 20% of the crude could be made into gasoline up to 1914, and its octane number was only 50. By 1922 improved refining processes and the addition of tetraethyl lead had increased the yield to 30% and the octane number to 65. Thermal cracking, whereby large, low-volatility molecules are broken up, came in 1925, increasing the yield to more than 40% and the octane number to 75. In 1935

the cracking process was improved with catalysts to raise the octane number to 85. Higher octane ingredients are made by converting highly volatile constituents into gasoline, making 100-octane fuel and nearly 45% yield possible. (*See* also PETROLEUM.)

Combustion Chambers.—While the petroleum industry was improving gasoline, engine manufacturers were improving combustion and fuel utilization. Modern gasoline engines resulted from the mutual adaptation of fuels and engines. The knowledge that higher compression ratio increases efficiency and output encouraged designers to increase compression ratios as rapidly as the fuel limitations and the engine requirements could be matched.

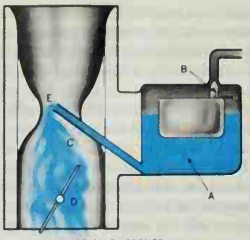
Combustion control in the spark-ignition engine is largely a matter of avoiding preignition and knocking. Self-ignition of the charge before the spark occurs is one of the extreme effects of increased compression ratio. Normal knock is a self-ignition effect, but it occurs after most of the charge has burned normally.

The tendency for a mixture of gasoline vapour and air to self-ignite increases with its temperature, density and the length of time that it is held at self-ignition temperature. In high-compression engines the temperature and density before ignition are much higher than in low-compression engines. The problem in attaining smooth, normal combustion becomes one of burning the charge by the normal flame front before it ignites spontaneously. Much depends upon resistance to self-ignition or octane number, but the severity of the conditions before and during combustion can be lessened by careful design of the combustion chamber and the induction system, as well as by improved cooling of surfaces that are contacted by the charge. The time element in self-ignition is important and can be controlled and shortened in several ways. The more compact the combustion chamber is made the shorter the distance that the flame front must travel to burn all of the charge. Locating the spark plug more centrally shortens flame travel to the boundary of the chamber. Increased engine speed causes more rapid combustion. All of these time-shortening factors are employed in reducing the octane requirements of engines.

The L-head engine was the first to which the principle of turbulence, charge concentration near the spark plug, shortened flame travel and quench area remote from the plug were applied. Sir Harry Ricardo conceived the L-head combustion chamber design shown in fig. 6 shortly after World War I, and it was widely adopted for engines of this type. The "squish turbulence," created by the close approach of the far side of the piston to the cylinder head, feeds most of the charge that would otherwise have been last to burn into the flame front and permits the remainder to be kept cool by proximity to the metal walls. As compression ratios are increased, however, reduced depth of the passage from the valves to the cylinder bore restricts the flow of charge, causing decreased power at high speeds. Manufacturers were forced to adopt the valve-in-head design, in which the charge flows directly into the main cylinder chamber from the valves, for engines with compression ratios higher than eight.

Two types of high-compression combustion chambers were developed for valve-in-head engines, the wedge type and the hemispherical type. All practical designs may be considered as modifications of these two types. The combustion chamber shown in fig. 7 is of the wedge type. The spark plug is located at a deep section, so that as much charge as possible can be burned initially, and tapers away to a region thinned out to gasket thickness designed to act as a quench area and to promote squish turbulence.

Carburetion.—The gasoline carburetor is a device that proportions fuel into the air stream as it flows into the intake manifold. A simple carburetor is shown diagrammatically in fig. 13. Gasoline is maintained in the float chamber A by the float-actuated valve B at a level slightly below the outlet of the jet C. Air flows downward through the throat, past the throttle valve D and into the intake manifold. A venturi throat is formed by the reduced diameter at E, and acceleration of the air through this smaller passage causes a decrease in pressure proportional to the amount of air flowing. This decrease in throat pressure results in fuel flow from jet C into the air stream. Any increase in air flow caused by change in engine speed or throttle position will increase the pressure differential acting on the fuel and cause more fuel to flow.



BY COURTESY OF O. C. CROMER

FIG. 13.—DIAGRAM OF SIMPLE ELEMENTARY CARBURETOR (*see* TEXT FOR FURTHER INFORMATION)

The volume ratio of air to fuel established by the throat and fuel jet sizes will be maintained with increased flow, but the weight of fuel per pound of air increases because the air expands to a lower density as the throat pressure decreases. This enriching tendency necessitates the inclusion of a compensating device in a practical carburetor. Carburetor design is further complicated by the need for an enriching device to provide a maximum-power ratio at full throttle, a choke to facilitate starting a cold engine, an idling system to provide the special needs of light-load operation and an accelerating device to supply additional fuel while the throttle is being opened.

Fig. 14, a sectional view of a typical automobile engine carburetor, shows the throttle in the idling position and indicates the flow of fuel through the idling circuit which draws fuel from the top of the float chamber and delivers it past an idle-adjusting screw to a point in the carburetor outlet just below the throttle valve. When the throttle valve is closed a high vacuum exists on the manifold side of the valve which causes the idling circuit to function.

As the throttle is opened the vacuum at the idle fuel outlet is so reduced that no fuel flows from it and fuel is supplied only by the main jet. The small air flow at the venturi throat when the throttle is closed is insufficient to cause fuel to flow from the main jet, but this jet comes into operation as the throttle is opened.

Fig. 15 shows the carburetor functioning normally with the throttle more fully open and fuel flowing through the main metering jet and into the air stream at the main discharge jet. The high-speed bleeder admits air into the fuel passage as a means of preventing enrichment at increased rates of flow.

Only the idling and main-fuel circuits are shown in these two views. Accelerating and full-throttle enriching devices and other components are present but not visible.

Modern automobile carburetors are further complicated by the provision of two or four throats, commonly called barrels, as a means of improving charge distribution over the wide range from

FIG. 15.—SECTIONAL VIEW OF A CARBURETOR SHOWING MAIN METERING SYSTEM

idling to full throttle. A dual carburetor has two throats, each of which supplies half of the cylinders. A four-barrel carburetor is in effect a small dual carburetor at less than half throttle and a large carburetor when the throttle is more fully opened and the other two barrels are cut in.

Fuel Injection.—Gasoline-injection systems were available for airplane engines before World War II and were extensively used. The performance of engines with this equipment was excellent, but the much greater cost of fuel-injection systems as against carburetors limited their application. Efforts to simplify and cheapen fuel-injection equipment without impairing performance yielded multicylinder pumps that could compete in cost with the four-barrel carburetor. Gasoline-injection equipment has been designed in a variety ranging from distributor systems employing a single pump for all of the cylinders to multipump types.

The principal advantages of gasoline injection over the carburetor are: (1) improved fuel economy because of more accurate fuel and air proportioning; (2) greater power because of elimination of charge heating; (3) elimination of inlet icing; and (4) more uniform and direct delivery of charge to the cylinders.

The SU fuel-injection pump, developed in England, is representative of the direct gasoline-injection systems available. An injection nozzle, located just outside each intake valve, is supplied with fuel at pressures up to 200 p.s.i. in metered quantities while air is entering the cylinder. The basic metering principle is to vary the amount of gasoline delivered to each cylinder in accordance with engine speed, manifold pressure and temperature of the air in the inlet manifold. This is known as speed-density metering and assumes that the rate of air flow to an engine is nearly proportional to its speed and to the density of the air as it enters the cylinders.

A cross section of the SU fuel-injection pump is shown in fig. 16 with the important parts identified. Pump bores, each with a closely fitted plunger, are spaced in a circle about the central drive shaft with their axes parallel with the shaft. The plungers are held against a wobble plate by springs and receive their reciprocating motion from the angle through which the plate rocks as the main shaft rotates. This angle, in turn, depends upon the axial displacement of the servo piston and its oblique extension through the plate. Upward motion of the piston displaces the plate laterally, causing its ball-section upper surface to assume a more level position, thereby shortening the strokes of the plungers.

The axial location of the servo piston is established by the intake-manifold pressure in the capsule chamber above and the gas pressure within the capsule created by the temperature bulb located in the manifold.

When the throttle at the entrance to the inlet manifold is opened the manifold pressure rises, compressing the capsule, moving the pin shaft upward and opening the oil supply so that pressure is applied under the servo piston. The wobble plate is then tilted at a greater angle and pumping capacity is increased. Higher manifold pressure causes the piston to assume a higher position and higher air temperature lowers it, delivering fuel in proportion to the air density.

There are half as many pump barrels and plungers as there are cylinders in the engine and the pump shaft turns at crankshaft speed. A distributor valve between the pump barrels and the delivery lines to the injectors is moved so that the fuel is delivered to half of the cylinders during one turn of the shaft and to the other half on the next turn. Thus each pump delivers fuel alternately to two cylinders that fire one crank turn apart. Fuel flows to each injector nozzle for 180° of crankshaft rotation, timed to occur within the period of inlet-valve opening. Fuel flow into the pump chambers on the plunger upstrokes is also controlled by the distributor valve.

Ignition.—Two types of electric ignition systems are used, the magneto and the battery and coil systems. They are similar in principle but the magneto is self-contained and requires only the spark plugs and connecting wires to complete the system, whereas the battery and coil system involves several separate components. Fig. 17 shows a six-cylinder battery, coil and distributor system. The circuit consists of a 6- or 12-v. battery, one terminal of which is grounded while the other leads through a switch to the primary winding of the coil, and then to the circuit breaker where it is again grounded. Current flows through the primary circuit when the switch is closed and the points of the circuit breaker are in contact. Rotation of the circuit-breaker cam opens and closes the primary circuit. The secondary circuit starts with the secondary winding of the coil (several thousand turns of very fine wire), one end of which is connected to the primary winding while the other leads

to the rotor of the distributor which acts as a rotary switch, selecting the spark plugs to be placed in the circuit. Each plug is connected to one of the outer terminals of the distributor to receive an electrical impulse in proper sequence.

When the breaker points are in contact, current flows through the primary winding, creating a magnetic field that crosses the turns of the secondary winding. Separation of the breaker points by the cam breaks the circuit and causes the magnetic field to collapse rapidly, inducing a voltage across each turn of the coil. A total potential as high as 20,000 v. is built up in the secondary winding at the instant that the breaker points open and is applied to the rotor of the distributor. This rotor is in phase with the circuit-breaker cam so that it establishes a circuit to one of the spark plugs just before the breaker points separate, and then moves on to the terminal leading to the next spark plug in firing sequence.

A considerable voltage is also induced in the turns of the primary winding when the breaker points open, causing a spark to occur at the points just as they are separating. This spark tends to burn and pit the breaker points, so a capacitor or condenser is connected across the circuit breaker to protect the points.

A spark plug consists of a threaded steel shell that screws into the cylinder head and an insulator that contains a central electrode. A gap of .02 to .04 in. is provided between the central electrode and the ground electrode attached to the shell of the plug. The central electrode extends through the insulator to receive the secondary wire from the distributor, and the circuit is completed from the ground electrode through the metal of the engine to the battery and thence to the coil. The voltage established at the coil must be sufficient to jump the spark-plug gap against the resistance of the compressed charge.

The spark must be precisely timed in the cycle of the engine; the timing is established by the gear train connecting the breaker cam to the camshaft and thence to the crankshaft. The optimum time for the spark to occur varies both with the load on the engine and with its speed, necessitating an advance mechanism to vary the timing with changes in operating conditions.

A centrifugal flyweight device advances the spark timing as the engine speed increases and a vacuum device advances the timing as the throttle is closed, utilizing the increase in intake manifold vacuum as load decreases.

Ideally, the charge should burn instantaneously while the piston is at top dead centre. Time required for the flame to travel across the combustion chamber permits the crankshaft to turn through 30° to 40° during combustion. Highest thermal efficiency is attained when the pressure rise in the cylinder resulting from combustion is half completed by the end of the compression stroke. The start of the combustion pressure rise is then 15° to 20° before top dead centre on the compression stroke and the peak of firing pressure occurs at the same angle after top dead centre. Any change in operating conditions that slows flame travel and lengthens the burning period requires that the spark be timed earlier to permit combustion still to be at top dead centre.

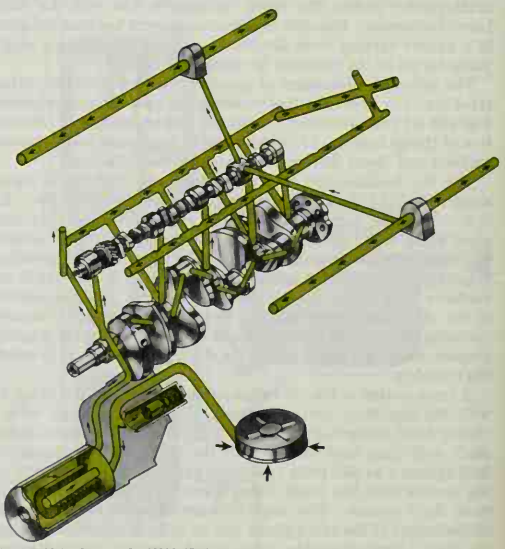
If the octane number of the gasoline fails to meet the requirements of the engine, knock can be minimized with slightly later spark timing. When the spark is retarded, burning occurs later in the cycle (more fuel is burned early in the power stroke and less in the last part of the compression stroke). The piston then will have descended slightly before the last portion of the charge is burned and the resulting expansion of the remaining charge will prevent it from reaching knock temperature and density. Power and efficiency suffer if spark timing is retarded beyond the optimum, but this loss is preferable to knock.

The increased severity of ignition requirements resulting from increases in engine speed and compression ratio as well as the problem of maintaining circuit-breaker points of high-mileage commercial vehicles have led to the development of transistorized ignition systems. In the simpler of these systems the transistor is used to start and stop the current through the primary coil. The breaker points are used only to trigger the transistor and operate at very low current with little maintenance attention. The circuit breaker is entirely eliminated in a more elaborate system. A magnetic pulse generator is incorporated in the distributor assembly to produce timed electrical pulses that trigger the transistor and allow the primary current to flow through the coil when each spark is required.

Lubrication.—The purpose of lubrication is to interpose a film to reduce friction that would quickly destroy rubbing parts. The lubrication system must continuously replace the films that separate the parts.

The lubricant commonly employed is refined from the nonvolatile fractions of crude oil after the fuels are removed. Its viscosity must be appropriate for each engine and the oil must be suitable for the severity of its operating conditions. Oils are improved with additives that reduce oxidation, inhibit corrosion and act as detergents to disperse deposit-forming gums and solid contaminants.

A system of SAE (Society of Automotive Engineers) numbers, from 5 to 50, is used to designate oil viscosity; the lower the number, the lighter the body of the oil. The letter W after the number indicates that the oil is suitable for winter use. W oils are rated



BY COURTESY OF CHRYSLER CORPORATION

FIG. 18.—ENGINE LUBRICATION SYSTEM FOR 1964 CHRYSLER CORPORATION V-8 ENGINES

according to their flow rates at 0° F.; other types are tested at 210° F. Multirated oils, such as 10W–30, contain additives that oppose the tendency to thicken at low temperature, making the same oil satisfy both summer and winter requirements.

Automobile engine lubricants are also classified according to the severity of the operating conditions for which they are suitable by the code letters ML, MM, and MS. The ML grade is recommended for light-duty service, MM for moderately severe conditions, and MS for severe conditions. These oils differ principally in the types and quantities of additives. Diesel engines operate under unusually severe conditions and require special lubricants that are similarly classified as DG, DM and DS. A DG oil is equivalent to an MS oil.

Oil filters, if regularly serviced, can remove solid contaminants from crankcase oil. However, chemical reactions may form liquids that are corrosive and damaging. Depletion of the additives also limits the useful life of lubricating oils.

The lubrication system is fed by the oil sump that forms the lower enclosure of the engine. Oil is taken from the sump by a pump, usually of the gear type, and delivered under pressure to a system of passages or channels drilled through the engine. In some instances a full-flow filter runs the length of the engine between the pump and the main oil passage. In other engines bypass filters continuously bleed off a small quantity of oil and return the filtered oil to the sump.

Oil is supplied under pressure to crankshaft and camshaft main bearings. Adjacent crank throws are drilled to enable the oil to flow from the supply at the main bearings to the crankpins. Leaking oil from all of the crankshaft bearings is sprayed on the cylinder walls, cams, and up into the pistons to lubricate the piston pins. Additional passages intersect the cam follower openings and supply oil to hydraulic valve lifters when used. A spring-loaded pressure-relief valve maintains the pressure at the proper level.

Gas Engines.—Gas is burned in some large stationary power plant engines and automotive types used in trucks, buses and tractors. Stationary gas engines are used extensively where natural gas is available at favourable prices. Also, natural gas used with spark-ignition engines is more resistant to self-ignition than other fuels, permitting higher compression ratios to be used with greater efficiency and economy. Low-cost power is important in these engines, and brake thermal efficiency exceeding 40% is reported, more than is claimed for other engines.

Large stationary power plant engines were originally of the cylinders-in-line type, but space requirements and cost considerations led to the development of V type and horizontal radial engines.

Fig. 19 shows a cross section of a radial engine with a vertical crankshaft directly connected to a direct-current generator. This is a two-stroke-cycle engine with 12 cylinders and 14-in. bore and 16-in. stroke, developing up to 2,125 h.p. and 1,500 kw. at 400 r.p.m. Scavenging and charging are through two sets of ports in opposite sides of the cylinder walls and poppet valves are eliminated.

Salient features of the radial engine are high power output per unit of floor space, low weight, high mechanical efficiency because of few bearings, single-throw crankshaft and nearly perfect balance. Operation on natural gas with spark-ignition at a compression pressure of 275 p.s.i. and a maximum cylinder pressure of 650 p.s.i. is possible because of the high antiknock quality of the fuel and the lean mixtures used. Gas is supplied at 20 p.s.i. to mechanically actuated gas inlet valves located above the inlet ports in the top surfaces of the cylinders that admit the fuel into the stream of scavenging air brought in from headers below the floor. Spark plugs at the top and bottom of each cylinder head fire at slightly different angles before top dead centre. A unique feature of this engine is the restraining linkage that prevents rotation of

FIG. 19.—SECTIONAL VIEW OF A RADIAL SPARK-IGNITION GAS-BURNING ENGINE

the single master bearing to which the inner ends of the connecting rods are pinned.

Automotive gas engines cannot operate on natural gas under low pressure because of the large volume of gas that would have to be carried. These engines can use propane-butane mixtures that are liquefied by compression to about 185 p.s.i. These gases are important by-products of petroleum refinery operation and are available as liquefied petroleum gases (LPG). Gases with similar liquefying characteristics also are taken from the ground at petroleum wells. The supply of these gases exceeds demand and, particularly in oil-producing regions, they are priced below the cost of gasoline.

The necessity of storing LPG in steel bottles or cylinders designed to withstand 250 p.s.i. is a serious handicap; nevertheless excellent combustion characteristics for spark-ignition engines make LPG attractive. High antiknock quality, high heating value per pound and high volatility give LPG excellent performance characteristics. The antiknock quality permits compression ratios several units higher than are practical with gasoline, resulting in better efficiency and economy.

The fuel system requires, in addition to the heavy steel container, pressure regulators, a vaporizer heated by the engine coolant and a gas carburetor. The fuel is supplied to the vaporizer as a liquid and is prevented from freezing during vaporization by the heat received from the coolant. The LPG carburetor is simpler than the gasoline carburetor because special compensating devices are unnecessary.

INTERNATIONAL, THE. The International is a federation of working-class parties aiming at the transformation of the capitalist societies into socialist commonwealths and their unification in a world federation.

The Forerunners.—The idea of a democratic, egalitarian International sprang from the ideas of the French Revolution of 1789. In England it inspired the London Corresponding society, the first independent working-class movement, founded by the shoemaker Thomas Hardy in Jan. 1792, and in France the *Conspiration des Égaux*, the first essentially socialist movement, founded by François Noel Babeuf in Nov. 1795.

Suppressed during the period of reaction, the idea of establishing a revolutionary democratic International revived in France and England after the July revolution in 1830. Auguste Blanqui and Armand Barbès founded the secret *Société des Saisons* in 1837, with which the *Bund der Gerechten*, formed with branches in Switzerland by German artisans one year before, was closely associated. After an unsuccessful rising engineered by both these associations in 1839, the leaders of the *Bund der Gerechten* moved from Paris to London where, under the guidance of Karl Marx and Friedrich Engels, they revived it as the Communist League (1847–52). Marx wrote the *Communist Manifesto* as its program. At about the same time there emerged from the Chartist movement the Society of Fraternal Democrats (1846–50), directed by George Julian Harney, and after it expired, the International association (1855–59), founded by the poet and Chartist leader Ernest Jones.

The First International.—The First International, set up at a mass meeting at St. Martin's hall in London on Sept. 28, 1864, under the name of International Workingmen's association, was merely another of the attempts to establish a working-class International. Its founders were Henry Louis Tolain, an influential leader of Paris workers' organizations, George Odger, then president and later secretary of the London Trade council, and a number of the most powerful British trade union leaders. Marx had no part in planning the meeting though he was invited to attend it. He was elected as one of the 32 members of the general council and at once assumed its leadership. In a statement known as the "Inaugural Address" he proclaimed that "the great duty" of the working class was to conquer political power and "to vindicate the simple laws of morals and justice, which ought to govern the relations of private individuals, as the rules paramount to the intercourse of nations." The provisional rules which he drafted declared that the economic emancipation of the workers was the great end to which every political movement should be subordinated, and that the purpose of the association was "the protection, advancement, and complete emancipation of the working classes." Five years later, at its Basel congress in 1869, the International adopted socialist aims: the transformation of the private property of the land and forests into public ownership and the socialization of the mines and railways.

The First International assumed the character of a highly centralized party, based primarily on individual members, organized in local groups, which were integrated in national federations, though some trade unions and associations were affiliated to it collectively. Its supreme body was the congress (held at Geneva in 1866, Lausanne 1867, Brussels 1868, Basel 1869 and The Hague 1872). A general council elected by the congress had its seat in London and served as the executive committee; it met weekly, appointed corresponding secretaries for each of the national federations, issued statements of policy, organized collections for the financial support of strikes in various countries and was instrumental in preventing the importation into Great Britain of foreign workers as strikebreakers.

Its congresses were chiefly concerned with the formulation of principles designed to guide the working classes in their social and political struggle. They discussed the role of trade unions and cooperatives in the working-class struggle for emancipation; the question of nationalization of key industries and of the land; the attitude toward war; and, in particular, the role of the state as an instrument of social transformation and the question of workers' participation in parliamentary elections as a means of conquering the power of the state. The attitude of the International to these questions was laid down in resolutions. It was a unifying force of labour, stimulating the growth of trade unions and infusing into the working classes the sense of international solidarity.

Its renown, spreading rapidly all over Europe and the U.S., was, however, out of proportion to its numerical strength and financial resources. In the public eye, the first International appeared to be a formidable power with millions of members and almost unlimited resources. However, the hard core of its individual members exceeded hardly a score of thousands and its annual income scarcely £100. Yet it was held responsible for the waves of strikes that swept France, Belgium and Switzerland in 1868, and above all, for instigating the rising of the Paris Commune in March 1871. In fact, its general council in an "address" to the French workers, drafted by Marx, had appealed to them to abstain from any revolutionary action, and the Paris section of the International had indeed played no part in the insurrection that brought about the Commune. In Germany and Austria adherence to the International was prosecuted as high treason even before the rise of the Commune; after its fall, it was proscribed also in France and Spain. Jules Favre, French minister of foreign affairs, and the German chancellor Otto von Bismarck proposed to the European powers in 1871 that the International be outlawed by concerted action. The proposal failed only because the British government rejected it and refused to expel the foreign members of the general council residing in London.

From its beginnings, the First International was riven by conflicting schools of socialist thought: Marxism, Proudhonism, Blanquism (whose adherents joined it only in 1871) and, above all, Mikhail Bakunin's version of anarchism which dominated its Italian, Spanish and French-Swiss federations. Over the clash between Marx's centralized socialism and Bakunin's anarchism the first International split at its Hague congress in 1872. In order to prevent the Bakuninists from gaining control of the International, the congress, prompted by Marx, moved its headquarters to New York; there it lingered on until it was formally disbanded at the Philadelphia conference in July 1876.

The Bakuninists, assuming the leadership of the International,

held congresses at Geneva in 1873, Brussels 1874, Berne 1876 and Ghent 1877. At the Ghent congress the Social Democrats broke away because their motion to restore the unity of the International was rejected by the Anarchist majority. The Anarchists failed, however, to keep the International alive. After the London congress in 1881 it ceased to represent an organized movement. Yet the Anarchist ideology retained its hold among the French, Italian and Spanish trade unions until it finally perished as a social force in the Spanish civil war (1936–39).

The Second International.—The formation of Socialist parties on a national scale in various countries started only after the end of the first International. The Social Democratic party of Germany was formed by the unification of Ferdinand Lassalle's and August Bebel's groups in 1875, the French Socialist party in 1879, the Dutch and Danish Social Democratic leagues in 1878. The Spanish Socialist party appeared in 1879, the British Social Democratic federation in 1880, the Belgian Labour party in 1885, the Swiss Social Democratic party in 1888, the Austrian Social Democratic party in 1889, the Norwegian and Swedish Social Democratic parties in 1887 and 1889, and beyond the Atlantic the Socialist Labor party of North America in 1877.

The Second International, founded at a congress in Paris in 1889, was, unlike the first, based on membership of national parties and trade unions only. It was not a centralized organization, like the first, but rather a loose federation which, only 11 years after its foundation set up an executive body: the International Socialist bureau (I.S.B.) with Émile Vandervelde of Belgium as its president and Camille Huysmans, also of Belgium, as its secretary. Its headquarters were in Brussels. The founding congress in Paris in 1889 was followed by congresses in Brussels 1891, Zürich 1893, London 1896, Paris 1900, Amsterdam 1904, Stuttgart 1907, Copenhagen 1910 and Basel 1912. At that time the International represented the Socialist parties of all European countries, the U.S., Canada, Argentina and Japan, with an aggregate voting strength of nearly 9,000,000.

Although the Second International had no mandatory power, it was recognized by its member parties as their highest moral authority. Thus the debates and decisions of the congresses influenced to a great degree the ideology, methods and policy of the European labour movement. The Second International stood for parliamentary democracy and finally expelled the Anarchists (at the London congress in 1896) who opposed it. It rejected, however, the theory of gradual achievement of socialism and co-operation with nonsocialist parties in office, as advocated by Jean Jaurès, and reaffirmed the Marxist doctrine of the class struggle and the inevitability of social revolution.

Its main concern was, however, the prevention of war. It embarked on a powerful campaign against armaments and the danger of war; it demanded the introduction of compulsory courts of arbitration for the settlement of disputes between nations, the reduction of armaments with total disarmament as the ultimate aim, the abolition of secret diplomacy and the establishment of parliamentary responsibility in matters of foreign policy. Yet it rejected the use of the general strike for warding off an imminent danger of war, propagated by Keir Hardie, Édouard Vaillant and Jaurès. However, in a resolution drafted by V. I. Lenin, Rosa Luxemburg and Julius Martov and adopted by its Stuttgart congress in 1907, it pledged its member parties in belligerent countries to utilize the social and economic crisis brought about by war to promote social revolution.

But the power grouping in World War I confronted the Socialist parties in the belligerent countries with a dilemma. Each party felt that its own country was threatened by conquest of a formidable reactionary power: Germany and Austria by tsarist despotism, France, Great Britain and Belgium by autocratic Prussian militarism. Without hesitation all of them (except the Russian and Serbian Socialists) voted for the war credits in their respective parliaments and supported their governments in the war effort. Thus the fundamental principle of international working-class solidarity was superseded by national solidarity.

This attitude was, however, soon opposed by a growing minority within these parties; in Germany there was a split over this issue. In an attempt to restore international working-class solidarity, Italian and Swiss Socialists convened a conference of "Internationalists," held at Zimmerwald, Switz., in Sept. 1915, which, in a manifesto, rebuked the majority Socialists for straying from the principles of the International and appealed to the workers to struggle for the immediate cessation of the war and for peace negotiation based on the principle: "No annexations, no indemnities." Another conference of the same groups met at Kienthal, Switz., in April 1916.

The Socialist minorities opposing the war were divided in their attitude toward the nature of the action to be taken. The "Centre"—led in Germany by Hugo Haase and Karl Kautsky, in France by Jean Longuet, in England by Ramsay MacDonald and in Austria by Friedrich Adler—insisted on the general concept of socialist internationalism and the resumption of the class struggle. The "Left," led by Lenin, who had attended both the Zimmerwald and Kienthal conferences, demanded the launching of revolutionary propaganda among the workers and soldiers and the "transformation of the imperialist war into civil war." He opposed the revival of the Second International, which had ceased to function when war broke out, and suggested the creation of a new International. He failed, however, to carry the conference; it set up an International Socialist commission charged with the task of cooperating with the I.S.B. in galvanizing the Second International into action for a speedy peace.

The outbreak of the Russian Revolution in March 1917, and Pres. Woodrow Wilson's declaration of the "fourteen points" issued when the U.S. entered the war in April 1917, imparted a tremendous impetus to the socialist peace movement. In Aug. 1917, leaders of the Dutch and Scandinavian Socialist parties jointly with the I.S.B. and the Petrograd Soviet issued an invitation for a general international socialist conference to be held in Stockholm in order to consider socialist peace aims and the means to end the war by negotiations. The invitation was accepted by the Socialist parties in Europe and the U.S. and, despite Lenin's appeal to reject it, also by the Zimmerwald groups. Yet the conference never assembled; the governments of Great Britain, the U.S., France and Italy refused to grant passports to the delegates.

Under the impact of the Bolshevik Revolution of Nov. 1917, the left wing of the European labour movement greatly increased its strength. In Germany, Austria and Hungary, there were large-scale strikes in Jan. 1918, followed by a mutiny in the Austrian navy a month later; in Britain, the Labour party for the first time adopted a socialist program; in France the "Internationalists" assumed the leadership of the Socialist party; and in Italy, the Socialist party adopted a Bolshevist program based on the "dictatorship of the proletariat." The rising left-wing tide in the countries of the central powers swelled up in revolutions which swept through Bulgaria, Hungary, Germany and Austria in Oct. and Nov. 1918.

In an attempt to reconstruct the Second International, Socialist leaders of the Allied countries convened a conference, which met at Berne in Feb. 1919, attended by 97 delegates from 26 countries. It set up a commission charged with the task of preparing a congress of the International. However, when it met at Geneva in July 1920 it was revealed that it represented only a small fraction of the prewar members of the Second International. The rift in the international socialist movement, produced by dissensions over the war policy pursued by the majority of the Socialist parties, and their hostility to the Bolshevik Revolution, which had aroused the sympathy of great masses of workers, had destroyed the common ground for the reinstitution of the Second International. Delegates of the "Centre" and "Left" Socialist parties—among them the Socialist parties of France, Austria, Switzerland and the German and British Independent Labour parties—which had refused to join either the Second or the Communist International met in congress in Vienna in Feb. 1921 and formed the International Working Union of Socialist Parties (or Vienna union) with the object of preparing the ground for an all-embracing International.

The Communist International.—The Communist International, known as the Comintern or Third International, was founded at a congress in Moscow in March 1919. It was attended

only by 19 groups chiefly from countries of eastern and central Europe; no major Socialist party outside Russia was represented. It elected a temporary executive committee with Grigori Zinoviev as president and Angelica Balabanoff as secretary. In a manifesto, it denounced the "Centre" Socialist parties even more strongly than the "Right" and called upon the workers to join the Communist International for the immediate overthrow of capitalism.

The second Comintern congress, assembled in July 1920, met under more promising auspices. In Germany, Austria, Czechoslovakia, Bulgaria, Sweden, the Netherlands, Finland and the U.S., sections of the Socialist parties had broken away and had formed Communist parties, and in the Socialist parties of France, Italy, Norway and Spain, the pressure in favour of joining the Comintern had greatly increased. During 1920 there were general strikes in the Balkans, a Communist uprising in the Ruhr, mass strikes and seizures of factories in Italy, and a general strike in France, while at the same time in Russia the Red army had defeated the White armies and had invaded Poland. The "world revolution" appeared to be on the march. In this atmosphere several hundred delegates from 37 countries flocked to the congress—delegates not only from Communist parties but also from the Socialist parties of France, Italy, Norway, Switzerland, the British Independent Labour party and the German Independent Social Democrats.

Lenin was resolved to forge the Comintern into the spearhead of the world revolution, according to the pattern he had devised for the structure of the Bolshevik party. In his "twenty-one points," endorsed by the congress, he laid down the conditions of admission to the Comintern, such as the adoption of a strict Communist program, the removal of all "reformists" from responsible positions in the labour movement, the undertaking to engage in illegal work, to disrupt the armed forces and, above all, to submit to "iron discipline" under the control of the executive committee of the Comintern, which was in turn controlled by the politburo of the Russian Communist party. Over the controversial issue of the acceptance of the "twenty-one points," the German Independent Social Democratic party and the Socialist parties of France, Italy, Norway and Czechoslovakia split.

But the world revolution anticipated by the second Comintern congress failed to materialize; the single Communist rising which occurred in Europe, the rising of the German Communists in March 1921, collapsed ingloriously and accentuated the internal dissensions in Communist ranks. The European Socialist parties on the whole succeeded in repulsing the Communist onslaught. At the same time, the Soviet Union was beset with grave internal troubles: a rapid decline in production; peasant resistance against compulsory delivery of grain; growing discontent of the workers, culminating in the Kronshtadt revolt in March 1921; and the formation of a "Workers' Opposition" inside the Russian Communist party.

To ward off imminent disaster, Lenin introduced the New Economic Policy (N.E.P.), which abolished the requisitioning of grain and restored private trade. He also recognized, at the third Comintern congress in June 1921, the Communist failure to win the masses of the workers by a frontal attack on the Socialist parties alone. He proposed the tactics of the United Front, which, while emphasizing the need of struggle in co-operation with Socialist workers for immediate demands, retained the policy of attacking and splitting the Socialist parties. A conference was held in Berlin in April 1922 to explore the conditions of common actions. It was attended by representatives of the Second, Third and Vienna Internationals but it failed to bridge the gulf between democratic socialism and Communist dictatorship. The United Front tactics accentuated, however, the latent dissensions between the left wing, which opposed it, and the right wing of the Communist parties; it utterly collapsed after the defeat of a Communist uprising in Germany in Oct. 1923. In France, Czechoslovakia, Germany and other countries, the left, supported by Zinoviev, captured the leadership of the Communist parties.

But the failure of the German October uprising finally sealed the fate of the Communist hope for a world revolution which had been regarded by Lenin and Leon Trotsky as a precondition for the ultimate triumph of socialism in Russia. The N.E.P. had been introduced only as a "temporary retreat." In the struggle for power between Trotsky and J. V. Stalin after Lenin's death in Jan. 1924, the left-wing leadership of the main European Communist parties supported Trotsky and Zinoviev in their opposition to Stalin's policy of "socialism in one country." Stalin triumphantly removed Zinoviev as president from the Comintern in 1926, replaced him by the right-wing leader N. I. Bukharin and expelled the left leadership in the Communist parties in 1927. But he soon turned against Bukharin, who opposed the forcible collectivization of the peasants, and crushed him together with the right-wing leadership of the Communist parties. In 1929 Stalin's nominees, V. M. Molotov, Dimitri Manuilski and Otto Kuusinen, assumed control of the Comintern apparatus; after that date the Comintern became exclusively an instrument of the Russian state. At the same time, convinced that the world economic crisis in the early 1930s heralded the final collapse of capitalism, Stalin initiated a period of "left-wing extremism." The Communists concentrated their main efforts on liquidating the Social Democratic parties, and in Germany they co-operated with the Nazis in the destruction of the Weimar republic.

But after Adolf Hitler's rise to power, Stalin, afraid of a German attack, returned to the United Front tactics. In France the Communists supported the alliance of left and centre parties which, under Léon Blum's premiership, formed a Popular Front government in June 1936. But at the same time they harassed it by instigating large-scale strikes. In Spain they supported the republican government against the revolt of Gen. Francisco Franco, yet once they had succeeded in gaining control of the police force, they exterminated the revolutionary anti-Communist wing of the republican movement. After the Nazi occupation of Czechoslovakia in March 1939 the tension between Nazi Germany and the western powers increased and war appeared to be imminent. Stalin then negotiated a pact with Hitler that ensured Communist support for the Nazis' war effort. This pact remained in force until the Nazi invasion of Russia in June 1941. The Communists, infiltrating the underground resistance movement in the countries occupied by the Nazis, emerged from the war with greatly increased strength, particularly in France, Italy and Czechoslovakia.

In the meantime, the Comintern, which had not met in congress since 1935, was officially dissolved in May 1943. But in Sept. 1947 a new centre of international control—the Communist Information bureau or Cominform—was set up and initiated a new phase of revolutionary aggression. The Communists expelled from the government in France organized revolutionary strikes there and in Italy, and seized power in Czechoslovakia by a *coup d'état* in Feb. 1948, thus completing the process of imposing Communist regimes in all countries occupied by the Soviet army. After Tito's defection in June 1948, the Cominform slowly faded out. Thus the last remnant of the Communist International as a formal organization, which at least pretended to grant its member parties the right to participate in shaping its policy, ceased to exist. Moscow reasserted its sole control of international communism, assumed already by Stalin before the war, to be rejected only by the Chinese and Albanian Communists.

The Labour and Socialist International.—After the failure of the Berlin conference (April 1922) of the three Internationals, the Second International and the Vienna union drew closer together and ultimately united at a congress held in Hamburg in May 1923, attended by 620 delegates representing 43 parties in 30 countries with an aggregate membership of 6,700,000 and a voting strength of 25,000,000. It adopted the name "Labour and Socialist International" (L.S.I.). It was, according to its constitution, "a union of such parties as accept the principles of the economic emancipation of the workers from capitalist domination and the establishment of the Socialist Commonwealth as their object." The congress elected Arthur Henderson, leader of the British Labour party, as president, to be followed by Émile Vandervelde, leader of the Belgian Labour party, and Friedrich Adler as secretary. The International Federation of Trade Unions (I.F.T.U.) founded in Amsterdam in Aug. 1919 was also represented at the congress and pledged its co-operation with the L.S.I. The Hamburg congress was followed by congresses in Marseilles (1925), Brussels

(1928), Vienna (1931) and a conference in Paris (1933).

The L.S.I. saw in fascism the gravest menace to freedom and peace and considered the restoration of working-class unity as the most effective means to combat it. Yet the fundamental differences between the L.S.I. and the Comintern frustrated every endeavour to re-establish this unity. The L.S.I. recognized in the economic conditions of the Versailles peace treaty one of the main sources from which both the Communist and Nazi movements in Germany derived their strength, and strove for a fair settlement of the reparations imposed upon the Weimar republic. It called on the western powers to assist Germany when her economic fabric collapsed in the early 1930s. With Hitler's rise to power the L.S.I. became mainly preoccupied with the danger of war. It supported the principle of collective security, pressed for the adoption of a general convention of the League of Nations to strengthen the means of preventing war, and opposed the rearmament of Nazi Germany. In co-operation with the I.F.T.U. it organized financial assistance on a large scale for political refugees from fascist countries, especially for the victims of Franco's war against the Spanish republic.

Hitler's conquests in western Europe destroyed the basis of the International in Europe. Only the British, Swedish and Swiss Socialist parties survived. The International ceased to function.

The Socialist International.—After World War II the International was reinstituted in gradual stages, beginning with establishment of an information and liaison office at the first postwar international conference, held in England in May 1946, to be transformed into a consultative committee a year later and, finally, in 1947, into a more representative body called Committee of the International Socialist Conference, or Comisco. In March 1951 it decided to reconstitute the International.

This took place at a congress held in Frankfurt-on-Main, Ger., in July 1951. It assumed the name "Socialist International" (S.I.), and adopted statutes determining its structure and a declaration of the "Aims and Tasks of Democratic Socialism." It elected Morgan Phillips, secretary of the British Labour party, as president, to be followed by Alsing Anderson, vice-chairman of the Danish Labour party, and Julius Braunthal as secretary, succeeded by Albert E. Carthy. Three of the major member parties of the International are represented in its presidency by Hugh Gaitskell, leader of the British Labour party, Guy Mollet, leader of the French Socialist party, and Erich Ollenhauer, leader of the German Social Democratic party. Its headquarters were set up in London.

Unlike the provisions of the statutes of the L.S.I., according to which its decisions were binding on its affiliated bodies, the S.I. statutes require the consent of all member parties for resolutions. Whereas the L.S.I. statutes gave voting power to the individual parties according to the number of members they represented, the S.I. statutes allocate one vote to each member party regardless of its strength. The L.S.I. was closely associated with the I.F.T.U., but there exist no links or any form of co-operation between the S.I. and the International Confederation of Free Trade Unions (I.C.F.T.U.). Whereas the I.F.T.U. was composed of trade union centres which represented virtually Socialist members, the I.C.F.T.U. includes among its affiliates non-socialist bodies like the American Federation of Labor-Congress of Industrial Organizations (A.F.L.-C.I.O.) in the U.S., and Christian-Democratic trade unions in Italy and other countries.

The structure of the S.I. is, however, similar to that of the L.S.I. Its supreme body is the congress meeting every other year. It proclaims its principles, determines its statutes and decides by a two-thirds majority upon the admission of new members. A smaller body at which, however, each member party is entitled to representation, is the council of the S.I., which assembles at least once a year. Its functions include the formulation of the attitude of the S.I. toward current political issues, the election of the presidency and secretary and the fixing of affiliation fees. Finally, the bureau, composed of delegates from 12 countries and meeting according to requirements, is charged with the supervision of the secretary's activities.

In its declaration of principles the S.I. put the main emphasis upon the political aspects of socialism: democracy and civil liberty. But whereas the L.S.I., while opposing the Communist regime of dictatorship, acknowledged the Soviet Union as a revolutionary Socialist power and pledged the Socialist parties to resist attempts of war against her, the S.I. not only rejects the Communist system as irreconcilable with Socialist principles, but also supports the North Atlantic alliance against Russsia. The L.S.I. was striving for genuine co-operation with the Communists, but Comisco, in 1948, expelled the Socialist Democratic parties of Czechoslovakia, Bulgaria, Hungary and Rumania, because they had merged with the Communist parties, and the Italian Socialist party, because it refused to dissolve its pact of co-operation with the Communists; it admitted a group which had broken away from the Italian party in opposition to the pact and had formed the Social Democratic party of Italy. When the 20th congress of the Russian Communist party, held in Feb. 1956, expressed its desire for some form of co-operation with the Socialist parties, the S.I. in its statement of April 1956 reaffirmed its position, "which firmly rejects any united front or any form of political co-operation with the parties of dictatorship." However, it supports the policy of coexistence and general disarmament under international supervision.

Next to its preoccupation with the defense of democracy against totalitarian communism, the S.I. is mainly concerned with problems of colonialism and assistance to the underdeveloped countries. It declared its support of the colonial and dependent people's struggle for self-determination. Considering the economic plight of the industrially underdeveloped countries as a major humanitarian as well as a political problem, it adopted a detailed "World Plan for Mutual Aid" and pledged its member parties to arouse world opinion to induce the governments to carry it out through the United Nations agencies.

The S.I. stands for the economic unity of Europe, and the relevant European member parties participate in the activities of the European parliamentary assemblies: the Council of Europe, the Western European union and the European Coal and Steel community.

In 1960 the S.I. consisted of 40 Socialist parties in Europe, Asia (India, Israel and Japan) and in the Western hemisphere (Argentina, Canada, Jamaica, U.S. and Uruguay); it included also the New Zealand Labour party. The affiliated parties represented an aggregate of roughly 10,000,000 members and a voting strength of over 64,000,000. Integrated in the S.I. was the International Council of Social Democratic Women, representing 1,700,000 members in 19 countries, and a Latin American secretariat in Montevideo, Uruguay. It was closely associated with the Socialist union of central-east Europe, comprising Socialist parties in exile, the International Union of Socialist Youth, the International Union of Social Democratic Teachers and, in particular, the Asian Socialist conference. The latter was founded at a congress in Rangoon, Burma, in Jan. 1953, and was composed of the Socialist parties of Burma, Ceylon, India, Indonesia, Israel, Japan, Lebanon, Malaya, Nepal and Vietnam.

INTERNATIONAL COURT OF JUSTICE, the principal judicial organ of the United Nations, which succeeded the Permanent Court of International Justice after World War II. For generations eminent statesmen, private persons and various organizations—national and international—have devoted much

time and energy to efforts looking to the peaceful settlement of disputes between nations. Various methods of settlement have been advocated and at times resorted to, such as the use of good offices by other states, commissions of inquiry and conciliation, arbitration and judicial settlement.

Arbitration as a form of judicial settlement has been used by states over a long period of time—not generally but frequently. Many bilateral and a number of multilateral treaties and conventions providing for arbitration have been concluded from time to time, some relating to then-existing disputes and others relating to disputes or categories of disputes which might arise in the future. Of the multilateral conventions providing for arbitration those which stand out are the Conventions for the Pacific Settlement of International Disputes concluded at the first and second peace conferences held at The Hague in 1899 and 1907. The convention of 1899 contains provisions on the use of good offices and mediation, international commissions of inquiry and elaborate provisions designed to regularize arbitral procedure. It also provides for the establishment by the signatories of a panel of jurists called the Permanent Court of Arbitration (although in no sense a court) to which each state, party to the convention, should appoint four members, and from which governments desiring to arbitrate might choose competent arbitrators.

Although many international arbitrations both before and following the Hague conventions constitute landmarks in the process of peaceful settlement of disputes, and the tribunals in such cases made notable contributions to an international jurisprudence, it was recognized that with all its virtues a system in which reliance is placed on *ad hoc* tribunals, as distinguished from an established court of justice, was not all that might be desired. The situation, as visualized by him, was epitomized by Elihu Root, the U.S. secretary of state, who, in instructions to the U.S. delegation to the second Hague conference, observed that the principal objection to arbitration rested not upon the unwillingness of nations to submit their controversies to impartial arbitration, but upon an apprehension that the arbitrators would not be impartial. He instructed the delegates to try to have the Permanent Court of Arbitration developed into a permanent tribunal composed of judges "who are judicial officers and nothing else, who are paid adequate salaries, who have no other occupation and who will devote their entire time to the trial and decision of international causes by judicial methods and under a sense of judicial responsibility."

The 1899 convention was revised, but as revised it fell far short of the pattern outlined by Root. It did not provide for judges "who are judicial officers and nothing else" and who would "devote their entire time to the trial and decision of international causes." Rather it continued the system of a panel of jurists from which arbitrators might or might not be chosen for particular cases.

However, the 1907 conference prepared and recommended to the powers represented at the conference a draft convention to establish a court of arbitral justice composed of judges to be elected for fixed periods of service and on a salary basis. But the project was not adopted by the states and the court was never established. Nevertheless the draft had its influence on subsequent developments.

Permanent Court of International Justice.—The next notable step in the process of developing an international judiciary was taken by the League of Nations in 1920, when, pursuant to article 14 of the covenant of the League, it took steps to establish the Permanent Court of International Justice.

Article 14 provided:

> The Council shall formulate and submit to the Members of the League for adoption plans for the establishment of a Permanent Court of International Justice. The Court shall be competent to hear and determine any dispute of an international character which the Parties thereto submit to it. The Court may also give an advisory opinion upon any dispute or question referred to it by the Council or by the Assembly.

In Feb. 1920, the council appointed a committee of jurists to prepare a plan which it could submit to members of the League for adoption. The members of the committee were: Mineitciro Adatci (Japan), Rafael Altamira y Crevea (Spain), Raoul Fernandes (Brazil), Baron E. E. F. Descamps (Belgium), G. F Hagerup (Norway), Albert Geouffre de la Pradelle (France), B. C. J. Loder (Netherlands), Lord Phillimore (United Kingdom), A. Ricci-Busatti (Italy) and Sen. Elihu Root accompanied by James Brown Scott (United States).

The committee, following meetings at The Hague in June and July of that year, submitted to the council a draft scheme which, with certain modifications, was adopted by the council, and with still further amendments was approved by the assembly on Dec. 13, 1920. The text was attached to a protocol of Dec. 16, 1920, for signature and ratification by the members of the League. By Sept. 1921, the requisite number of states, a majority, had given their approval and the draft became the statute of the Permanent Court of International Justice.

The statute prescribed the qualifications for the judges, the method of election and tenure of office, the court's jurisdiction, its mode of procedure, etc. The first court, consisting of 11 judges and 4 deputy judges, was elected by the council and the assembly on Sept. 14–16, 1921. Later, in 1930, the assembly elected 15 judges and 4 deputy judges. Still later, following the coming into force in 1936 of amendments to the statute, the deputy judges were eliminated and the court was composed of 15 judges elected as theretofore by the council and the assembly.

The court held its first meeting at The Hague, its seat, on Jan. 30, 1922. It held annual meetings thereafter until its work was interrupted by World War II. Its last meeting, an administrative one, was in Oct. 1945.

During its existence it rendered 23 judgments and gave 27 advisory opinions. The court was open to members of the League and also to states mentioned in the annex to the covenant. The conditions under which it should be open to still other states were to be laid down by the council. Acceptance of the jurisdiction of the court was not compulsory. States were free to bring their disputes to the court or not as they might see fit. However, they were privileged, under the optional clause of article 36 of the statute, to declare, either when signing or ratifying the protocol to which the statute was adjoined, or at a later moment, that they recognized as compulsory *ipso facto* and without special agreement, in relation to any other state accepting the same obligation, the jurisdiction of the court in any or all of certain specified categories of disputes. Such declarations might be made unconditionally or on condition of reciprocity on the part of several or certain states or for a certain time. During the existence of the court some 29 states accepted the compulsory jurisdiction in varying forms and for varying periods of time. During this same period 47 states signed the protocol of 1920, to which the statute was annexed, and all but 8 ratified it.

The United States did not become a party to the statute of the Permanent court, although efforts to have it do so were made in turn by Secretaries of State Charles E. Hughes, Frank B. Kellogg and Henry L. Stimson, supported by Presidents Warren G. Harding and Herbert Hoover, as well as by many private citizens who felt that such a tribunal held great potentialities for peaceful settlement of international disputes. A senate resolution for adherence that came to a vote on Jan. 29, 1935, failed to obtain the requisite two-thirds vote, and no further action to have the United States become a party to the statute was taken. Yet throughout the period of the court a U.S. jurist was on the bench.

Judges of the Permanent Court.—During its existence, the court had on the bench the following named judges who served respectively for the periods indicated:

Rafael Altamira (Spain), 1922–45
Dionisio Anzilotti (Italy), 1922–45
Ruy Barbosa (Brazil), 1922–23
A. Sánchez de Bustamante (Cuba), 1922–45
Viscount Finlay (United Kingdom), 1922–29
Hans Max Huber (Switzerland), 1922–30
B. C. J. Loder (Netherlands), 1922–30
Mineitciro Adatci (Japan), 1931–34
D. G. G. Nyholm (Denmark), 1922–30
Yorozu Oda (Japan), 1922–30
C. A. Weiss (France), 1922–28
E. da Silva Pessôa (Brazil), 1923–30
Charles E. Hughes (U.S.), 1928–30
Henri Fromageot (France), 1929–45
Sir Cecil Hurst (U.K.), 1929–45
Frank B. Kellogg (U.S.), 1930–35
F. J. Urrutia (Colombia), 1931–42

W. J. M. van Eysinga (Netherlands), 1931–45
J. G. Guerrero (El Salvador), 1931–45
Demètre Negulescu (Rumania), 1931–45
E. Rolin Jacquemyns (Belgium), 1931–36
Michal Rostworowski (Poland), 1931–40
Walter Schücking (Germany), 1931–35
John B. Moore (United States), 1922–28
Charles de Visscher (Belgium), 1937–45
Wang Chung-hui (China), 1931–36
Åke Hammarskjöld (Sweden), 1936–37
Manley O. Hudson (U.S.), 1936–45
Harukazu Nagaoka (Japan), 1935–42
Cheng Tien-hsi (China), 1936–45
R. W. Erich (Finland), 1938–45

The deputy judges were:

F. V. N. Beichmann (Norway), 1922–30
Demètre Negulescu (Rumania), 1922–30
Wang Chung-hui (China), 1922–30
Mihailo Yovanovich (Yugoslavia), 1922–30
R. W. Erich (Finland), 1930–36
J. Caeiro da Matta (Portugal), 1930–36
Mileta Novakovich (Yugoslavia), 1930–36
Joseph Redlich (Austria), 1930–36

The court was authorized by the statute to elect its president and vice-president for three years. The presidents were: Loder (Netherlands), 1922–24; Huber (Switzerland), 1925–27; Anzilotti (Italy), 1928–30; Adatci (Japan), 1931–33; Sir Cecil Hurst (U.K.), 1934–36; Guerrero (El Salvador), 1937–45. The vice-presidents were: Weiss (France), 1922–28; Huber (Switzerland) 1928–30; Guerrero (El Salvador), 1931–36; Sir Cecil Hurst (U.K.), 1937–45.

Establishment of International Court of Justice.—Following World War II and the advent of the United Nations, the League of Nations was dissolved and with it the Permanent Court of International Justice. But that court was not dissolved until the new one—the International Court of Justice—had been established. By this time the nations, including the United States, were thoroughly convinced that a court of justice must have first rank in any organization for the maintenance of peace. This explains why the court was featured in the charter of the United Nations and why the statute was unanimously approved by the U.S. senate. Article 92 of the charter states:

> The International Court of Justice shall be the principal judicial organ of the United Nations. It shall function in accordance with the annexed Statute, which is based upon the Statute of the Permanent Court of International Justice and forms an integral part of the present Charter.

Article 93 provides that all members of the United Nations are *ipso facto* parties to the statute and states not members may become parties on conditions to be determined in each case by the UN general assembly upon recommendation of the Security council. The court consists of 15 judges, no two of whom may be nationals of the same state, elected by the general assembly and the Security council. They do not have life tenure as do members of the supreme court of the United States, for example, but are elected for periods of nine years and are eligible for re-election.

The seat of the court is at The Hague, but it may hold sessions elsewhere whenever it considers it desirable. Its first session was held at The Hague in April and May 1946.

It is a continuing body. The statute provides that it shall remain permanently in session, except during judicial vacations. It is also an autonomous body. It elects its president and vice-president, appoints its registrar and provides for the appointment of such other officers and clerical staff as may be necessary. The president and the registrar are required to reside at The Hague.

The Judges.—The judges, who must possess certain specified qualifications, do not represent the states from which they are chosen. They represent the entire international community of states. They are not selected by the governments of their states or even nominated by them; they are nominated rather by the national groups in the Permanent Court of Arbitration referred to above, or, in the case of states not represented on the Permanent Court of Arbitration, by national groups appointed for that purpose by their governments, the purpose being to remove the nominations as far as possible from political considerations.

Comparable safeguards were placed around the election of the judges. The statute provides that in such elections the general assembly and the Security council shall proceed independently of each other, and that at every election the electors should bear in mind not only that the persons to be elected shall individually possess the qualifications required "but also that in the body as a whole the representation of the main forms of civilization and of the principal legal systems of the world should be assured." Those candidates who obtain an absolute majority of votes in both the general assembly and the Security council are to be considered as elected. Further procedure is provided for the situation where, after the first meeting for the purpose of the election, one or more seats remain to be filled.

The judges receive annual salaries reasonably commensurate with their status. But they must be prepared to accept certain inhibitions; *i.e.*, they must refrain from all activities incompatible with their judicial functions. Specifically, they are forbidden to exercise any political or administrative function, or to engage in any other occupation of a professional nature; they are not permitted to act as agent, counsel or advocate in any case, and no member may participate in the decision of a case in which he has previously taken part as agent, counsel or advocate for one of the parties, or as a member of a national or international court, or a commission of inquiry, "or in any other capacity."

The purpose of the statute is to have at all times a court that is entirely free from bias or any preconceived notion as to the merits of any case coming before it. Each member is required, before taking up his duties, to "make a solemn declaration in open Court that he will exercise his powers impartially and conscientiously." In order to facilitate the proper exercise of their judicial functions the members, when engaged on the business of the court, enjoy diplomatic privileges and immunities. Members are bound to hold themselves permanently at the disposal of the court.

While nine judges constitute a quorum, the statute requires that the full court shall sit except when it is expressly provided otherwise. The court may dispense with the sitting of one or more judges "according to circumstances and in rotation," provided the number of available judges is not thereby reduced below 11. In practice, the full court sits in all cases except where a judge is disqualified by reason of some previous connection with the case or is prevented by illness or other serious reasons from attending. No judge may be dismissed unless in the opinion of all the others he has ceased to fulfill the required conditions. Vacancies resulting from death or otherwise must be filled by the same method as that laid down for the first election. A member elected to replace a member whose term of office has not expired holds office for the remainder of his predecessor's term.

Obviously, since there are only 15 judges, cases are sometimes presented by states which have no national on the court. While the statute provides that judges of the nationality of each of the parties retain their right to sit in the case before the court, it also provides that, if the court includes upon the bench a judge of the nationality of one of the parties, the other party may choose a person to sit as judge; also that if the court includes upon the bench no judge of the nationality of either party each of the parties may choose a person to sit as judge. This privilege is frequently exercised. *Ad hoc* judges receive compensation for each day on which they exercise their functions.

Competence.—Since the function of the court is to pass judgment upon disputes between states, only states may be parties in cases before the court. It is open to all states parties to the statute and to such other states as comply with conditions laid down by the Security council, which conditions must not, in any case, place the parties in a position of inequality before the court.

At the time that the statute was being drafted, there was strong sentiment on the part of certain states, particularly the smaller ones, for giving the court compulsory jurisdiction; *i.e.*, making it possible for any state to bring an action against any other state without the latter's consent. This, it was argued, was warranted by the more than 20 years of satisfactory experience with the Permanent court. The opponents of this view felt that some states were not yet ready to accept compulsory jurisdiction, and that to try to force it upon them might cause them to decline to accept

the statute at all. They favoured the adoption of the optional provisions in article 36 of the statute of the Permanent court. This was agreed upon, and that article became article 36 of the new statute. Under it parties to the statute may at any time file with the secretary-general of the United Nations a declaration accepting compulsory jurisdiction. A large number of states have done so. The declaration may be made unconditionally or on condition of reciprocity on the part of other states, or for a certain time. It was further provided in article 36 (paragraph 5) that declarations made under the old statute conferring jurisdiction on the Permanent court which were still in force should be deemed, as between the parties to the new statute, to be acceptances of the compulsory jurisdiction of the new court.

In 1946, when the U.S. senate was considering the exact nature of the court's jurisdiction, Sen. Tom Connally introduced a resolution providing that the United States should be free to determine for itself what matters were of an essentially domestic nature and thus outside the jurisdiction of the court. Senator Connally argued that such a self-judging reservation was necessary because the court might take a broad view of what was an international question and thus interfere with U.S. policy on immigration, tariffs and the Panama canal. Several other countries followed the U.S. example and reserved the right to determine what matters fell within their domestic jurisdiction. Criticism of the "Connally resolution" was frequently voiced in the United States and in other countries as being inconsistent with the principle that no one should be a judge in his own cause, and as indicating a lack of confidence in the court. Several countries that originally adopted the self-judging reservation later reconsidered and withdrew it.

The Anglo-Iranian Oil company case (*Great Britain* v. *Iran*) involved a declaration by Iran in 1933 under article 36 of the statute of the Permanent court. Although the court held that it did not have jurisdiction, it was only because it found that the declaration did not cover that particular case (judgment, July 22, 1952; ICJ Reports [1952] p. 93).

The court's jurisdiction was still further extended by article 37 of the statute, which stipulates that whenever a treaty or convention in force "provides for reference of a matter to . . . the Permanent Court of International Justice, the matter shall, as between the parties to the present Statute, be referred to the International Court of Justice."

The advisory opinion given July 11, 1950 (ICJ Reports [1950] p. 128), on the international status of South West Africa, and the judgment rendered July 1, 1952, in the Ambatielos case (*Greece* v. *Great Britain;* ICJ Reports [1952] p. 28) are examples involving article 37 of the statute.

States which have not accepted compulsory jurisdiction may not be sued without their consent. A state may give its consent by entering into an agreement with another state or otherwise indicating its willingness to submit the dispute to the court. *See* the judgment of March 25, 1948, in the Corfu channel case (*Great Britain* v. *Albania;* ICJ Reports [1948] p. 15).

In 1954 the United States filed with the court two applications instituting proceedings against the Soviet Union and Hungary, respectively, and in 1955 like action was taken against Czechoslovakia and the Soviet Union, respectively, each complaint relating to certain aircraft incidents; also in 1955 Great Britain filed two applications instituting proceedings against Argentina and Chile, respectively, concerning sovereign rights in the antarctic. None of the defendant states had accepted compulsory jurisdiction, and on being informed of these actions by the registrar of the court, each in turn specifically declined to submit the dispute to the court. In consequence, the court was under the necessity of issuing orders removing the cases from its list.

In 1959 the court held that it lacked jurisdiction over the claim of Israel for damages from Bulgaria for an airliner shot down over Bulgarian territory. In 1931 Bulgaria had accepted the compulsory jurisdiction of the Permanent Court of International Justice without time limit. The court held that this acceptance did not carry over to the present because Bulgaria had not joined the United Nations until after the statute of the old court had come to an end.

The statute declares it to be the duty of the court to decide disputes in accordance with international law. It applies: (1) international conventions establishing rules recognized by the contesting states; (2) international custom, as evidence of a general practice accepted as law; (3) the general principles of law recognized by civilized nations; and (4) it may look to judicial decisions and the teachings of the most highly qualified publicists of the various nations as subsidiary means for determining rules of law. It may also decide cases *ex aequo et bono* (that is to say, on the basis of equity), if the parties agree. In the absence of such an agreement it must apply rules of law.

Procedure.—The official languages of the court are French and English; either may be used by the parties. Written pleadings and oral arguments presented in one language are translated by the court's staff into the other. The judgments and opinions are in both languages.

Cases are brought before the court either by the notification to it of a special agreement concluded by the parties or by the unilateral action of one of them through a written application addressed to the registrar. The proceedings are in two parts, written and oral. The written proceedings usually consist of two pleadings on each side and supporting documents. Oral arguments by counsel follow the written proceedings.

The court may also hear witnesses and appoint commissions of experts to make investigations and reports when necessary. Both these procedures were followed in the Corfu channel case (*Great Britain* v. *Albania*) decided April 9, 1949.

The deliberations of the court are in private, but the judgments, which are by a majority vote, are read in open court. Any judge may file a separate opinion if he does not agree in whole or in part with the decision. Few decisions represent the unanimous opinion of the judges. The judgment is final and without appeal.

The question is frequently asked as to how decisions of the court are enforced. This also troubled the minds of some of the delegates at the United Nations Conference on International Organization, held at San Francisco, Calif., when the statute was under consideration. To meet their wishes there was incorporated in article 94 of the charter an undertaking on the part of each member of the United Nations "to comply with the decision of the . . . Court . . . in any case to which it is a party," and a further provision that:

> If any party to a case fails to perform the obligations incumbent upon it under a judgment rendered by the Court, the other party may have recourse to the Security Council, which may, if it deems necessary, make recommendations or decide upon measures to be taken to give effect to the judgment.

It should be remarked, however, that by the late 1950s there had been no known instance of the failure of a party to a case before the court, or before its predecessor, the Permanent Court of International Justice, to carry out a decision of either court. In the case of the Anglo-Iranian Oil company (*see* above), Iran declined to observe an order issued by the court, July 5, 1951, under article 41 of the statute, indicating interim measures of protection to be taken by the parties pending final decision. But this is not to be regarded as an exception to what has just been stated since such orders do not amount to judgments. They merely indicate provisional measures which the court considers ought to be taken to preserve the rights of the parties.

Advisory Opinions.—The court is authorized by article 65 of the statute to give advisory opinions on any legal questions at the request of whatever body may be authorized by or in accordance with the charter of the UN to make such a request.

Article 96 of the charter provides that such opinions may be requested by the general assembly or the Security council; also that they may be requested by other organs of the United Nations and specialized agencies, when authorized by the general assembly. Such requests must be laid before the court by means of a written request containing an exact statement of the questions, accompanied by all documents likely to throw light upon them. From this point on, the procedure before the court is somewhat analogous to that followed in contentious cases; that is to say, the registrar gives notice of the request to all states entitled to appear before the court, and the court or the president of the court fixes

time limits within which the states wishing to do so may submit written statements or be heard orally at a public sitting to be held for the purpose. States and organizations presenting written or oral statements are allowed, within a specified time, to comment on those submitted by others. Advisory opinions, like judgments, are delivered in open court.

Membership.—Article 13 of the statute provides that the members of the court shall be elected for nine years and may be re-elected, but in order to avoid the necessity of electing an entirely new court at the end of each nine-year period and to ensure that there shall be on the bench at all times a majority of experienced judges, it was further provided that of the judges elected at the first election, the terms of five should expire at the end of three years and the terms of five more should expire at the end of six years; also that the judges whose terms were to expire at the end of the said periods of three and six years should be chosen by lot to be drawn by the secretary-general of the United Nations immediately after the first election had been completed.

The first election was held on Feb. 6, 1946, at the London meeting of the general assembly and the Security council. Fifteen judges were elected. The procedure provided in article 13 was applied and five judges drew three-year terms and five others drew six-year terms.

In the middle 1960s the court was constituted as follows:

	End of term
Bohdan Winiarski (Poland)	1967
Abd al-Hamid Badawi (United Arab Republic)	1967
V. K. Wellington Koo (China)	1967
Jean Spiropoulos (Greece)	1967
Sir Percy Spender (Australia)	1967
Vladimir M. Koretsky (U.S.S.R.)	1970
Paul Kotaro Tanaka (Japan)	1970
J. L. Bustamente y Rivero (Peru)	1970
Philip C. Jessup (United States)	1970
Gaetano Morelli (Italy)	1970
Sir Gerald Fitzmaurice (United Kingdom)	1973
Luis Padilla Nervo (Mexico)	1973
André Gros (France)	1973
Mohammed Zafrulla Khan (Pakistan)	1973
Isaac Forster (Senegal)	1973

INTERNATIONAL CRIMINAL POLICE ORGANIZATION. This organization, better known as INTERPOL (originally its telegraphic address), is a body which exists to facilitate the co-operation of the criminal police forces of its approximately 90 affiliated countries in their fight against international crime. Its headquarters, the general secretariat, are in Paris and the supreme authority of the organization, the general assembly, meets once annually in a different capital city.

Aims.—The aims of the organization, to which almost all countries of the western world but none of the Communist countries except Yugoslavia belong, are: (1) to ensure and promote the widest possible mutual assistance between all the criminal police authorities of the affiliated nations within the limits of the laws existing in those countries; and (2) to establish and develop all institutions likely to contribute effectively to the prevention and suppression of ordinary crime. Interpol is strictly forbidden to undertake any political, military, religious or racial functions or activities.

Radio, television and motion pictures have presented Interpol as a vast mysterious international criminal investigation force, with agents throughout the world who can wander from country to country and make arrests wherever they please. This impression is quite false and represents an impossibility, since the nations of the world are sovereign states with varying legal systems and their criminal law, practice and procedure differ substantially. No sovereign state would permit any outside body to bypass its police or disregard its laws. The main weapon in the hands of the criminal police is not a universal detective: it is the extradition treaty.

Principally, Interpol's opponent is the international criminal, who falls into one of three main categories. First, criminals who operate in more than one country, crossing national frontiers to commit their crimes. Prominent examples are smugglers, dealing mainly in gold and narcotic drugs. Secondly, criminals who do not travel at all but whose crimes affect other countries. A good example is the forger of bank notes: a man may live in London all his life but make his living by forging U.S. dollar bills. Thirdly, criminals who commit a crime in one country and flee to another in an attempt to evade the consequences of their action. A man may commit a crime in Paris and yet be in London within two hours.

Organization.—The general assembly controls the policy of the organization, approves or rejects applications for membership, elects its executive committee, makes any necessary amendments to its constitution and discusses matters of interest to police of all nations.

The executive committee consists of nine delegates—a president, two vice-presidents and six members. The president holds office for four years and the other executive committee members for three years. The committee's duties consist of supervising the carrying out of the general assembly's decisions, deciding on its agenda for its annual meeting and exercising some control over the general secretariat.

The general secretariat, mainly staffed by officers from the French police and headed by a secretary-general, controls the everyday workings of Interpol. One of its principal functions is the collection, recording, analysis and dissemination of information, a function vital in criminal investigation everywhere. One of the main departments of the general secretariat is an International bureau to deal centrally with this operation. It has a criminal record office of international criminals and others who may later fall into that category, containing particulars of their identities, aliases, associates, method of working, etc., gathered from the police of the affiliated countries. This information is sent out to the countries likely to be interested by radio or by confidential circular.

Interpol has its own radio network, the central control station of which is situated just outside Paris and is linked to the other stations in such widely separated centres as London, Tel Aviv-Jaffa, Stockholm, Swed., and Rio de Janeiro, Braz. It also has an extensive code for enciphering messages.

The confidential circulars are of four types. The first asks for a particular criminal to be detained so that extradition proceedings can be started. The second does not ask for the criminal to be detained but gives full information about him and his methods to the police of countries in which he may temporarily be staying. The third does not deal with persons at all but with valuable property and may describe stolen jewelry or works of art which it is believed may have been smuggled out of the country in which the crime was committed. The fourth deals with unidentified bodies and attempts to discover their identity. A further section of the general secretariat, known as the Forgeries and Counterfeits office, is situated at The Hague.

Each affiliated country has a clearinghouse through which its individual police forces may communicate either with the general secretariat or with the police of other affiliated countries. This clearinghouse is known as the National Central bureau (N.C.B.). The N.C.B. for the United Kingdom and colonies, for example, is situated in the Metropolitan Police headquarters at New Scotland Yard, London, while that for the United States is the treasury department in Washington, D.C.

Development.—Interpol began in 1923 in Europe, which is not surprising since so many countries of Europe have common frontiers and a criminal can, for example, be in one of four other countries within an hour of having committed a crime in Belgium. Air travel greatly increased the means of escape to other countries. After World War I there was a great increase in crime. One of the countries most affected was Austria, and the Viennese police president, Johann Schober, obtained his government's support in 1923 for calling together representatives of the criminal police of other countries. The representatives of 20 nations attended to discuss the problems facing them and the International Criminal Police commission was formed. Vienna was the home of its first headquarters and Schober became its first president. From 1923 until 1938 the commission flourished.

In 1938 the Nazis seized Austria—and Interpol with it. All the records were taken to Berlin. The outbreak of World War II brought its activities to a standstill. After World War II, Florent Louwage, inspector general of police of the Belgian ministry of justice, quickly realized that international crime would once again increase. Austria, under four-power control, could not be considered as a headquarters and Belgium could not take the responsibility, but the French government offered Interpol a headquarters in Paris, together with a staff for the general secretariat consisting of officials of the French police. This offer was gratefully accepted. Interpol was thus revived under the presidency of Louwage assisted by an executive committee of four. Complete reorganization was necessary, since all prewar records had been lost or destroyed.

Interpol flourished and by 1955 the number of affiliated countries had increased from 19 in 1946 to 55. In that year the general assembly decided to draw up a modern and complete constitution, which was ratified in 1956. Under the constitution the name was changed to the International Criminal Police organization. The organization continued to progress and by the early 1960s the number of affiliated countries rose to 90, representing all the continents of the world. In particular the membership increased considerably during 1960–61, when several territories that had recently acquired their independence joined. (R. L. Ja.)

INTERNATIONAL FINANCE CORPORATION, an affiliate of the International Bank for Reconstruction and Development (*see* BANK FOR RECONSTRUCTION AND DEVELOPMENT, INTERNATIONAL). Its general purpose is to stimulate the economic advancement of underdeveloped member nations by providing venture capital for productive enterprises. It co-operates with private investors and business firms without the safeguard of governmental guarantees of loan repayment.

Background of the Organization.—The origin of the International Finance corporation (IFC) goes back to Pres. Harry S. Truman's request in 1950 that the U.S. International Development Advisory board recommend an appropriate U.S. policy toward economically backward regions. The board found that inefficient employment of locally available capital in the underdeveloped areas and inability of prospective foreign investors to obtain supplementary local venture (risk) capital were serious impediments to economic development. In March 1951 the board proposed the establishment of an International Finance corporation with authority to make nonvoting equity investments in local currencies in participation with private investors and to extend loans in local or foreign currencies to private firms. Unlike loans of the International bank, these investments would not require governmental guarantees of repayment.

Pursuing this recommendation, the United Nations Economic and Social council (ESC) in Aug. 1951 asked the International bank to submit an evaluation of the merits of such an agency. The bank's report of April 1952 concluded that the proposed corporation would "fill an important gap in the existing machinery for financing economic development." Consequently, ESC requested a continuing study of the proposal by the International bank.

During 1953–54 it became apparent to the bank that the needs of the underdeveloped areas for development funds were becoming increasingly acute. It was also obvious that countries that were to be major contributors of funds to the corporation had not yet indicated a willingness to participate in the scheme. In particular, the U.S. government objected, the treasury department being vigorously opposed to the proposal on the ground that a new institution was not needed. It was anticipated that an increased flow of private funds into the underdeveloped areas would render the proposed corporation unnecessary. Additionally, there was deep concern in the United States over the principle of equity participation and over the possible budgetary difficulties that might arise because of the size of the proposed U.S. contribution to the corporation's capital. Since U.S. participation was imperative, the bank searched for a compromise plan.

Late in 1954, Eugene R. Black, president of the International bank, offered a way out of the impasse. The "Black plan" proposed that the corporation should not be given authority to make equity investments but be endowed with the power to make investments yielding a return only if income was earned by the co-operating enterprise. Furthermore, when the co-operating venture became a profitable operation these investments could be sold to private purchasers who would have the option of converting them into capital stock. Thus, Black in effect suggested that the corporation invest in convertible income debentures; it need never acquire an equity position. Additionally, to obviate budgetary problems, the Black plan stipulated that the corporation should begin with an authorized capital of $100,000,000 rather than the $400,000,000 originally proposed by President Truman's advisory board. The compromise scheme thus provided the basis for overcoming the U.S. government's reluctance on budgetary grounds and allayed its fear of mixing government with private enterprise. Still, the basic concept of financing economic development with nonguaranteed venture capital was retained.

Incorporating these features, the articles of agreement of the IFC were approved by the directors of the International bank in April 1955. The articles were then submitted to the governments of the member countries of the bank, since they were the only countries eligible for membership in the corporation. The articles specified that the agreement would enter into force when at least 30 governments whose capital subscriptions totaled the dollar equivalent of at least 75% of the authorized capital had signed the articles and deposited instruments of acceptance with the International bank. The importance of the Black compromise plan becomes clear when it is noted that the U.S. share of the capital subscription was $35,168,000. The corporation could not function until the United States accepted the articles. On Dec. 5, 1955, the United States completed the necessary steps for membership, being the third country, after Canada and Iceland, to do so. When on July 20, 1956, both France and Germany deposited their acceptances, the IFC officially came into being with 31 member nations and a subscribed capital of $78,366,000. Actual operations did not begin until July 24 when the corporation's board of directors appointed Robert L. Garner, formerly vice-president of the International bank, president of the new corporation. Within five years the IFC had more than 60 members.

Investment Principles.—The IFC charter sets forth investment principles that its officers must observe. Since financing is not to be undertaken where sufficient private capital is obtainable on reasonable terms the lending activities of the IFC are largely restricted to the underdeveloped member countries. This implies, further, that prospective borrowers from the IFC must first seek other private capital. The IFC looks upon itself as being the last resort as a source of funds, not the first. Moreover, it is not permitted to assume managerial responsibility in firms in which it has invested except where such action is deemed necessary to protect its investment against default or insolvency. The corporation finances only enterprises that are predominantly private; it is forbidden to invest in government-owned firms or in firms in which the government is a significant participant. Unlike the U.S. Export-Import bank, the corporation cannot stipulate where the proceeds of its loans will be spent. (*See* EXPORT-IMPORT BANK OF WASHINGTON.) A corollary of this is that the funds supplied by the corporation can be used for either foreign or domestic payments, whereas both the International bank and the Export-Import bank normally finance only the direct foreign exchange requirements of a project. The corporation is also prohibited from financing an enterprise in a country if the member government objects to such financing.

An important set of guidelines follows from the corporation's over-all goal of making the greatest possible use of private capital for economic development. Accordingly, the corporation is empowered to undertake its financing on terms that it considers appropriate, taking into consideration the requirements of the borrowing firm, the risks to be assumed by the corporation, and the terms and conditions normally obtained by private investors for

similar financing. In consequence, the rate of return and other terms of the loan are negotiated in each individual case. Negotiation is undertaken, of course, with the view to making the financial burden of the borrowing enterprise as light as is feasible. Most corporation loans carry an interest charge of from 6% to 7% and maturity dates ranging from 5 to 15 years with additional income contingent upon the earning of profits by the enterprise. This is in contrast with the lending operations of the International bank, which has utilized fixed interest-bearing loans exclusively.

If the IFC is to make a substantial contribution to economic development its small subscribed capital must function primarily as a working reserve rather than as fixed capital. To achieve this goal the corporation seeks to revolve its funds by selling its investments to private purchasers whenever it can do so on satisfactory terms. Therefore, its investments must be attractive to investors and, consequently, its loans must earn returns commensurate with the risks assumed. As an added attraction, most IFC investments carry the right to convert into equity shares, although the corporation itself, except in rare circumstances, is prohibited from exercising this option. The corporation is also authorized to guarantee securities in which it has invested in order to expedite their sale. By making useful and profitable loans in the underdeveloped areas the IFC hopes to foster an affirmative attitude toward such investment on the part of private investors everywhere.

Recognizing the possible need for adding funds to the working reserves of the corporation, the charter empowers it to offer its own obligations for public sale. To provide modest protection for the corporation's capital its officers are instructed to seek a reasonable diversification of investments. All productive enterprises, manufacturing, financial, commercial and agricultural, are eligible for loans.

To minimize administrative costs of the corporation its officers provisionally decided that it would not consider investment proposals unless the new investment in the firm was at least $500,000 and the desired contribution of the corporation was to be at least $100,000. The maximum amount of a single corporation commitment is normally about $3,000,000. The desire to reduce operating expenses also explains the corporation's close working relationship with the International bank, whose technical and administrative staff are available to it. *See* also FOREIGN AID PROGRAMS; ECONOMIC DEVELOPMENT; CAPITAL, EXPORT OF.

INTERNATIONAL GEOPHYSICAL YEAR, commonly known as IGY, was the 30-month period July 1, 1957–Dec. 31, 1959, during which a world-wide program of geophysical research was conducted. Initially planned for the first 18 months of this interval, it was extended an additional year. The extension was called International Geophysical Cooperation (IGC-59).

The scope of IGY represented an unparalleled enterprise in international scientific co-operation. It involved co-operation among more than 70 nations, participation by about 30,000 scientists and observers and operation of several thousand scientific stations reaching from pole to pole.

IGY was directed toward a systematic study of the earth and its environment. Even as a single planet the earth is far from static. Earthquakes, large and small, subject it to noticeable stresses and strains; the oceans, seas and the land itself are subject to tidal pulls. Energized by the sun's heat, water passes from the solid state in glaciers and snow fields to a liquid form in seas and rivers and then becomes a vapour in the atmosphere. Great atmospheric and oceanographic circulation systems transport heat energy between the tropics and the high latitudes, equalizing the energy balance of the earth; the tropics receive more energy from the sun than can be reradiated, while the polar regions radiate to space more energy than received directly from the sun.

The sun plays a critical role in weather and climate as the driving engine of winds and currents. Invisible particles and radiations stream to the earth from the sun and outer space, affecting the ionosphere and the earth's magnetic field and causing the brilliant northern and southern lights. These conditions change as events vary in the universe and as the earth rotates about its axis, moves about the sun and is carried with the solar system in a vast trajectory about the centre of our galaxy.

To understand these phenomena better, to obtain thereby better control of man's planetary environment and to gain new insights into the nature of the cosmos, world-wide studies are needed. IGY included 11 fields of geophysics: aurora and airglow, cosmic rays, geomagnetism, glaciology, gravity, ionospheric physics, longitude and latitude determinations, meteorology, oceanography, seismology and solar activity. Each field requires measurement at many points on or above the earth's surface if a relatively complete view of the field is to be obtained. Simultaneous studies permit the establishment of correlations among the many phenomena.

In addition, two novel programs, rocketry and artificial earth satellites, involving all the fields associated with the upper atmosphere and solar-terrestrial relations, were part of the effort. IGY led to a significant expansion of sounding-rocket research and to the initiation of space exploration. Because no one nation could undertake so extensive an effort or overcome problems of national boundaries, IGY was necessarily a co-operative effort among scientists of many nations.

History and Organization.—IGY had two antecedents in the International Polar years of 1882–83 and 1932–33. Both of these were largely concerned with studies of the high northern latitudes. During the first International Polar year 12 stations were established by 11 nations in the arctic for studies of surface weather conditions, geomagnetism and the aurora borealis. Perhaps the most significant result of this effort was the discovery that auroral lights occurred most often and vividly in a circular belt about the north magnetic pole and about 1,200 mi. below it. During the second International Polar year about 20 nations organized expeditions, and the number of observation stations in the northern latitudes was considerably increased. For example, about 90 meteorological stations were active in the arctic and 30 geomagnetic stations in latitudes above 60° N. In addition to the three fields investigated in the first International Polar year, studies of ionospheric physics were included in the second International Polar year. Using a device that transmitted short pulses of radio energy to the ionosphere and received the reflected signals, physicists gained new insight into the electrified layers between 40 and 200 mi. above the earth. Appreciable advances were made, using radiosondes, in the understanding of arctic weather and its relationship to weather in lower latitudes.

Advances in instrumentation during the three decades following the second International Polar year had made possible sensitive and more precise measurements. High-altitude balloons extended the range of radiosondes to about 100,000 ft. and special balloons could carry cosmic ray instruments even higher. Rockets were successfully used in the decade following World War II for direct exploration of the atmosphere up to heights of 250 mi. Automatic high-speed computers capable of analyzing the vast quantities of data were becoming available. These and many similar devices suggested that considerable progress could be made in studying geophysics on a broad basis. As early as 1950 informal discussions were held by geophysicists (led by the American, L. V. Berkner) looking to a third polar year. Proposals to this effect were considered by the International Scientific Radio union and the International Union of Geodesy and Geophysics.

Accordingly, the parent body of international scientific organizations—the International Council of Scientific Unions—sanctioned the broader study of the International Geophysical year and established a special committee (Comité Special de l'Année Géophysique Internationale) for IGY consisting of scientific representation from organizations concerned with radiophysics, astronomy, geodesy and geophysics, physics and geography, and the World Meteorological organization. The officers of this committee were Sydney Chapman (president), L. V. Berkner (vice-president) and

Marcel Nicolet (secretary-general). The first meeting of the special committee took place in Brussels, Belg., in July 1953 and was followed by a series of general assemblies and regional conferences. At the general assemblies, in particular, criteria for the IGY program were established. These criteria specified that: first, fields of geophysics were to be studied where data were needed from many points on or above the surface of the earth in order to get a planetary view; second, projects were to be undertaken that would yield results of value to former studies, such as rocket and satellite exploration of the upper atmosphere and near space; third, advantage would be taken of expeditions to remote places; in large part seismology and gravity measurements were introduced to capitalize upon opportunities opened up by IGY in the antarctic, the arctic basin and at sea; finally, epochal measurements were to be made; such measurements, as of snow and ice in glaciers, repeated at intervals over many years, could indicate long-range trends in climate.

National committees were established by scientific organizations in each country, and these groups solicited support from their governments and private institutions. In Great Britain, for example, the Royal society established a committee of experts. In the United States, the National Academy of Sciences assumed responsibilities for the effort and received contributions from many public and private organizations, including the National Science foundation (through which congress appropriated many millions of dollars) and the department of defense (which contributed extensive logistics and technical support, particularly in arctic, antarctic, rocket and satellite operations).

More than 70 nations co-operated in IGY; the following 66 national groups were formal participants: Argentina, Australia, Austria, Belgium, Bolivia, Brazil, Bulgaria, Burma, Canada, Ceylon, Chile, China (Taipei), Colombia, Cuba, Czechoslovakia, Denmark, Dominican Republic, East Africa, Ecuador, Egypt, Ethiopia, Federal Republic of Germany, Finland, France, German Democratic Republic, Ghana, Greece, Guatemala, Hungary, Iceland, India, Indonesia, Iran, Ireland, Israel, Italy, Japan, Democratic People's Republic of Korea, Malaya, Mexico, Mongolian People's Republic, Morocco, Netherlands, New Zealand, Norway, Pakistan, Panama, Peru, Philippines, Poland, Portugal, Southern Rhodesia, Rumania, South Africa, Spain, Sweden, Switzerland, Tunisia, Union of Soviet Socialist Republics, United Kingdom, United States, Uruguay, Venezuela, Democratic Republic of Vietnam, Republic of Vietnam, Yugoslavia. These nations were responsible for the operation of more than 2,500 major scientific stations as well as several thousand small or temporary stations and the participation of more than 10,000 scientists and technicians and several thousand amateur and volunteer observers. It is estimated that the IGY research effort cost about $500,000,000.

IGY studies dealt with (1) the physics of the upper atmosphere, which includes solar activity, and particles and radiations from the sun, other stars and the interplanetary medium; (2) the heat and water regimen, which includes meteorology, oceanography and glaciology; and (3) the earth's structure and interior, which includes seismic, gravimetric, and longitude and latitude determinations. In addition to these areas, some work in biology, environmental medicine and geology was conducted in the arctic and antarctic.

Particularly in the first two categories, measurements and observations were conducted on regular, daily schedules. Because the IGY period was chosen to coincide with the maximum sunspot cycle, when solar flares and disturbances are prevalent, the role of the sun was especially significant. To study these disturbances and their effects, provisions were made for intensifying observations in a program called World Days. Indications of unusual solar activity were flashed from any IGY station to a World Warning agency operated by the national bureau of standards at Ft. Belvoir, Va. There such reports were evaluated; if major disturbances in the upper atmosphere were anticipated, warnings were radioed to all stations in the world-wide network. These stations then increased the frequency of their regular measurements of the earth's magnetic field and of the ionosphere, sent up balloons to detect increases in cosmic ray intensities and auroral activity and launched rockets to intercept the particles and radiations from the sun. The special days or periods for such intensified observation were known as World Meteorological Intervals, Regular World Days and Special World Intervals.

World Meteorological Intervals were periods of ten consecutive days each, in June, September, December and March. They coincided with two pentads (five-day periods) of the World Meteorological organization and always included either a solstice or equinox, periods during which intensified meteorological observations are most desirable.

Regular World Days were three or four days each month that constituted a representative sample of the IGY period. Two were consecutive days at the time of the new moon; the others were at times of unusual meteor showers (Geminid, Perseid, Taurid, etc.) or near one of the lunar quarter phases. They also included the days of solar eclipse, with adjacent days for control purposes.

Periods of Alerts and Special World Intervals were designated on a day-to-day basis. A period of Alert was declared whenever solar activity was unusually high. During the period of Alert, an Interval would be declared whenever the possibility was high that an unusual geomagnetic storm would begin within a few hours. Each period of Alert and Interval continued until terminated by the World Warning agency.

The Upper Atmosphere.— The region of space between about 20 and 600 mi. above the

WORLD-WIDE NETWORK OF COMMUNICATIONS STATIONS WHICH CO-OPERATED IN STUDIES OF SOLAR DISTURBANCES AND THEIR EFFECTS DURING THE IGY

Indications of unusual solar activity were flashed to the central warning agency at Ft. Belvoir, Va. (Stations were located near major cities shown on map)

earth is largely dominated by particles and radiations from stars and interplanetary space. The sun emits a broad spectrum of radiations and particles that affects the earth and its atmosphere. Solar disturbances, particularly sunspots and flares, often result in magnetic storms, heightened auroral displays and ionospheric variations that frequently disrupt long-range radio communications, and they sometimes intensify cosmic rays. IGY solar investigations were designed to monitor solar activity so that warnings could be issued of disturbed or unusual conditions, to make measurements of solar phenomena and to relate these observations to the sun itself and to events in the upper atmosphere. Thirty-one nations made solar observations at 120 stations.

A world-wide solar flare patrol network was established. Flares are considered most significant in their terrestrial effects. Solar radio noise, cosmic radio noise and propagation of atmospheric noise were also observed. Variations in the spectral lines of certain major flares were recorded, and an effort was made to map the magnetic-field pattern of the sun on a day-to-day basis.

A variety of instruments were used in the IGY auroral studies. Twenty-nine special cameras photographed the sky, recording spatial distribution and changes of the aurora. Hundreds of amateur observers assisted in plotting the extent of auroral displays. Radar devices were used to scan the skies in cloudy weather and during daylight. Spectrographs and spectrometers analyzed the auroral variations. The objectives of these studies were to map the aurora in the north and south, to learn more about its origin and to correlate auroral events with other atmospheric and solar phenomena and disruptions in radio communication. In addition to hundreds of visual observation sites, over 140 instrumented stations were in operation.

Airglow at its brightest resembles faint aurora, but results from chemical reactions in the upper atmosphere rather than the charged solar particles that generate aurora. Sensitive photometers and high-speed spectrographs were in use at 50 stations to detect airglow. The nature and distribution of airglow were principal interests of IGY scientists in this field.

The component of the earth's magnetic field in space was studied during IGY because it is highly variable and interacts with the ionosphere, cosmic rays and the charged particles responsible for aurora. More than 250 magnetic observatories were active in IGY, and rockets and satellites were also used to carry instruments aloft. Particular attention was directed to rapid magnetic-field fluctuations, which are usually accompanied by disturbances in radio-wave propagation and by auroral displays. The fluctuations vary with the number of sunspots, and seem to be caused by three great electrical currents, hundreds of thousands of amperes in strength, flowing through the upper atmosphere, two moving in the high latitudes and one around the equator.

The region between about 50 and 200 mi. above the earth includes the ionosphere, so called because radiations from the sun create charged ions in the atmosphere at that level. The region behaves toward radio waves much like a mirror toward light waves, and accounts for the long-range propagation of radio waves by reflection. The ionosphere consists of several layers of varying ion density. Variations in the electron density of these regions, fluctuations in their heights, relationships to magnetic storms and solar phenomena were topics of study at about 250 stations with ground-based electronic devices and rockets. The chief instrument for ionospheric research is the ionosonde. Radarlike pulses are directed vertically to the ionosphere, and the reflections are recorded. The pulses are varied in frequency so that a broad band of the spectrum can be studied. The travel time of the pulses and their reflections provide virtual ionospheric heights (which are greater than the actual heights because of retardation of the pulses by the ionized medium) while phase shifts and intensities yield information on the state of ionization in the layers. Such studies lead to better knowledge of the ionosphere and provide the basis for selecting desirable frequencies for long-range radio communication.

Cosmic rays, which bombard the earth continuously from every direction, were studied at 130 stations. One of the difficulties in studying cosmic rays is the masking influence of the lower atmosphere. The primary rays fail to reach the earth because they collide with particles in the high atmosphere, creating secondary rays in a kind of chain reaction. In general it is these secondary rays that are observed on earth. More cosmic ray primaries enter at high latitudes where the magnetic field is more or less parallel to particle trajectories and fewer of the lower-energy particles are deflected away. At low latitudes, where the magnetic field is more or less perpendicular to particle trajectories, most of the low-energy particles are deflected, giving rise to the cutoff effect. IGY investigations were concerned with fluctuations in cosmic ray intensity with the sunspot cycle, intensity decreases during some magnetic storms, increases shortly after the onset of solar flares and chromospheric eruptions and mass-energy determinations. These studies employed neutron and meson telescopes, cloud and ionization chambers, photographic emulsions and Geiger counters.

Heat and Water.—Weather and climate are produced by interaction of the sun's energy and the lower atmosphere (below 20 mi. or so), the oceans, and snow and ice fields. These relationships also affect sea levels, ocean currents and the food stocks of the seas.

In meteorology, networks of 650 upper-air, 700 radiation and 100 ozone stations made temperature, pressure, humidity and wind observations and measurements. Circulation of the atmosphere and interchanges between the tropics and polar regions were studied. The objectives were to obtain world-wide data leading to improvements in forecasting, and to provide a sounder approach to climatic trends.

LAUNCHING A GIANT IGY WEATHER BALLOON

The purposes of the IGY oceanographic program were to gain an understanding of oceanic circulation and of both short- and long-duration changes in sea level and their relationships to other oceanic and atmospheric phenomena. Thirty-five countries operated 70 research vessels and 225 tide stations in these investigations. Measurement of the movement of deep waters occupied much attention, for these currents are important in the transport of considerable energy. Sea levels provide one key to oceanic circulation and to its meteorological influences. Sea-level changes were recorded at several hundred island stations.

Glaciers exist on all continents except Australia. Fluctuations in their extent provide clues to past and future climatic changes, while polar ice sheets act as sources of cold or sinks of heat from the tropics. Projects were under way to determine the volume of the ice sheets of Antarctica, Greenland and the arctic pack; to study the heat and water exchanges between these ice bodies and the atmosphere; and to examine snow stratigraphy, ice movement, temperature and topography. Eighty-three stations were in operation.

The Earth's Structure and Composition.—Better knowledge of the earth's interior was another objective of IGY. Seismologists of 50 nations gathered earthquake information from almost all regions, particularly from such areas as Antarctica where data were almost completely lacking. Man-made explosions were used to study seismic waves, and to determine ice thickness and the structure of underlying terrain. About 240 stations co-operated in this program of simultaneous land and sea measurements.

The size and shape of the earth remain imperfectly known. Because the earth is not uniform, the pull of gravity varies from place to place. Gravity measurements thus permit better determinations of the configuration of the earth, and almost 200 sta-

tions co-operated in the gravity program. Similar to ocean tides but much smaller, earth tides are created by the moon and sun. Hawaii, for example, rises and falls about four inches daily. Studies of these movements by gravimetry help to determine the rigidity of the earth and its internal structure.

To improve knowledge of distances between points and land masses, 70 stations engaged in longitude and latitude measurements. Twenty stations used a new instrument—the dual-rate moon-position camera, which permits position determinations within a few hundred feet by using the moon as reference. Standard astronomical techniques were also used, where local gravity surveys had provided a precise knowledge of the direction of the vertical, to obtain precisions to better than five feet. Such precision is basic in studying possible motions of the continents and also has applications in the making of maps.

Rockets and Satellites.—Prior to World War II knowledge of the upper atmosphere was restricted to indirect observations from or near the ground. During the decade following, research rockets were developed, largely in the U.S., to carry instruments as high as 250 mi. Several hundred such rockets were fired during IGY by Australia, Canada, France, Great Britain, Japan, the U.S. and the U.S.S.R. Data were telemetered back to earth and provided new knowledge in meteorology and atmospheric structure, ionospheric physics, aurora and airglow, geomagnetism, cosmic rays, and solar ultraviolet light and X-rays.

Rockets are particularly useful in measuring the altitude variation of such phenomena as temperature. They are restricted, however, by their brief lives and by their essentially vertical coverage. To overcome these limitations, IGY included satellite vehicles in the program. Satellites can traverse vast expanses over appreciable periods of time.

The inclusion of satellites in the IGY was recommended (1954) by the IGY general assembly at Rome. Both the U.S.S.R. and the U.S. responded and discussions of IGY plans for satellite research were under way in Washington, D.C., when, on Oct. 4, 1957, Sputnik I was successfully launched by the Soviet Union.

During the 30-month IGY interval the U.S. launched eight satellites and made three space probes. The experiments provided significant data concerning cosmic rays, magnetic fields, radio wave propagation, solar radiations and particles, cloud cover, heat radiation balance, micrometeorites and composition of the ionosphere. In the same period the Soviet Union launched four satellites and made two space probes, instrumented to observe similar phenomena. Two U.S. space probes (Pioneers IV and V) and one Soviet probe (Lunik I) became artificial planetoids of the sun. The U.S.S.R. Lunik II hit the moon on Sept. 13, 1959.

Results.—In several fields, notably meteorology and ionospheric physics, IGY data were immediately applicable and also provided information for future work such as the study of ionospheric storms and atmospheric circulation. Weather observations, for example, were promptly used in forecasting. A significant achievement was the preparation of twice-daily weather maps, providing the first census of antarctic weather. Recording of antarctic temperatures to a low of at least −86.7° C. (−124° F.) as well as studies of temperature, pressure, humidity and winds in both the arctic and antarctic provided data that can reveal the influence of these regions on world weather. In the period following IGY, daily weather maps for the entire globe, prepared by the weather services of the U.S., South Africa and the Federal Republic of Germany (assuming responsibility for the northern hemisphere, southern hemisphere and the equatorial belt, respectively), represented a powerful tool for understanding the forces that affect weather.

Using seismic sounding techniques, traverse parties ranging over thousands of miles in Antarctica measured ice thickness and secured a profile of underlying land masses. One hundred miles east of IGY Byrd station, in the heart of Marie Byrd Land, the ice measured 14,000 ft. thick, resting on bedrock 8,000 ft. below sea level. This is believed to be the thickest ice ever measured. It appeared that the antarctic might be a complex of island and mountain chains, some of which would lie hidden beneath sea level were the ice to melt. There were indications of a major division between east and west Antarctica. Seismic measurements revised the estimate of the amount of snow and ice in the world to about 4,500,000 cu.mi., about 40% higher than earlier estimates.

SEISMOLOGIST READING GRAVIMETER WITH WHICH TIDAL MOVEMENT OF ICE SHELF AT LITTLE AMERICA WAS DETECTED DURING THE IGY

In the arctic, gravimetric and seismic measurements uncovered an underwater ridge several thousand feet high. Three major countercurrents in the oceans were found and measured. One in the Atlantic flows beneath and opposite to the Gulf stream at a rate of 8 mi. per day about 9,000 ft. beneath the surface. The second, at depths between 200 and 1,000 ft., flows against the surface equatorial current of the Pacific, transporting 1,000,000,000 cu.ft. of water per second. The third lies beneath the surface 200 mi. north of the Pacific equator, transporting 1,500,000,000 cu.ft. per second. Millions of square miles of the southeast Pacific were found to bear a surface-bottom sludge laden with nodules of manganese and iron with up to 1% of cobalt mixed with copper. The value of these minerals was estimated at about $500,000 per square mile, and the economics of dredging up the sludge appeared promising.

The sounding rocket program of IGY permitted the detection of X-rays and auroral particles high above the earth, penetrated and observed the current sheets of the equatorial ionosphere and provided the first detailed photographs of the solar ultraviolet spectrum taken from above the masking layers of the lower atmosphere.

Pressure, temperature, composition and density were recorded to altitudes reaching about 200 mi. from several rocket-launching facilities. Rockets were used to probe active auroras and yielded data that showed, for example, that the soft radiation flux above 25 mi. is many times the flux of primary cosmic rays. Rockets also augmented the study of secondary cosmic rays on the ground, and both rockets and balloons recorded the intensities and composition of the primary radiation. The earth's magnetic field was measured in disturbed auroral regions, and atmospheric electric currents were recorded about the equatorial zone. Within the ionosphere, better electron density data were obtained, and the diffusive separation of atmospheric components below and above its E-region was measured. In astronomy, rockets provided new knowledge of solar radiations and of ultraviolet radiation emanating from other stars. Sodium vapour was ejected from rockets into the high atmosphere, permitting study of its diffusion, of high-altitude winds and effects on the vapour under the impact of particles and radiations from space. In the Argus experiment, electrons released by small atomic devices carried aloft by rockets showed how charged particles are trapped by the earth's magnetic field.

The discovery of the Van Allen radiation belts, in which both satellites and deep space probes were used, provided the basis for a unified description of variations of the earth's magnetic field, the aurora and solar particles. The inner Van Allen belt was first delineated by instruments aboard the early Explorer satellites. The radioactive particles appear at an altitude of 70 mi. in northern latitudes and 250 mi. above the equator and reach a maximum concentration at about 2,400 mi. C. Störmer had postulated that charged particles could be trapped in the earth's field and forced to spiral between northern and southern mirror points. But without experiment, his calculations could not be assessed. Now it appears that over a period of time the number of captured particles can increase appreciably, accounting for the formation of a Van Allen belt. It is probable that at least part of the inner belt arises from beta decay of cosmic rays.

With space probes Pioneers III and IV the second Van Allen belt was discovered to range from 6,000 to 36,000 mi. beyond the earth's surface. This outer zone showed a great increase in radiation intensity between observations of Pioneer III (launched during a relatively quiet period of the sun) and Pioneer IV (launched five days after a period of very high solar activity). The particles in this zone leak out near the magnetic poles and collide with atmospheric atoms, generating auroral displays. The Van Allen belts also explain latitude variations in temperature at high altitudes. IGY rocket experiments showed temperatures of about 2,000° K. over Ft. Churchill, Can., in contrast to 1,100° K. over White Sands, N.M., between altitudes of 90 and 120 mi.

Observations of the earth's shape with the first small Vanguard satellite permitted J. A. O'Keefe and his associates to postulate a pear-shaped model of the earth. The apparent variation from the previous theoretical model was small, but it was important in terms of the earth's structure and surface loading.

Both the U.S.S.R. and the U.S. provided valuable data on satellite drag and such environmental conditions as temperature. For example, L. G. Jacchia established definite relationships linking Vanguard I drag with both solar flux and magnetic activity index. Soviet satellites also permitted ionospheric studies in which the receptions can be coupled with precise positional data.

OCEANOGRAPHERS DROP A WEIGHTED DEVICE FROM THE IGY SHIP "VEMA" TO COLLECT SEDIMENT FROM THE OCEAN FLOOR

Specific discoveries and findings represent only a part of the technical results of IGY. Most of the effort involved collection of world-wide synoptic data. In one ionospheric physics project (vertical incidence soundings), 10,000,000 frames of film, each containing hundreds of bits of data, were accumulated. An even larger body of data was involved in the meteorology program, and comparable masses of data were collected concerning aurora and airglow, geomagnetism, cosmic rays and oceanography. Valuable analyses of such data were possible with automatic computers and associated techniques.

Thousands of published papers appeared as a result of IGY. Three centres for the interchange of data were established: in the U.S. under the auspices of the National Academy of Sciences, at the Soviet academy in Moscow and in western Europe (with a few discipline branches in Australia and Japan). Each centre gathered, indexed and archived a complete set of all IGY data. The task of interchange was finished on Dec. 1, 1961; final catalogues were published and distributed by each centre within six months. The centres made data available on request to all investigators. As studies of the data lead to new discoveries, these data continue as a unique reservoir for future research. To make the data even more generally accessible, publication of the *Annals of the IGY* was undertaken. These are largely devoted to compilations of significant quantitative as well as qualitative information. About 50 volumes were planned in the first stages of the work.

Politically, IGY is recognized as the basis for the Antarctic treaty, signed by 12 nations active in Antarctica. The treaty consecrates the polar region to peaceful, scientific uses and is the first instance in which such a portion of the earth has been so set aside. The United Nations also noted the value of IGY and recognized post-IGY activities planned by the international scientific community.

IGY itself directly generated new international organizations through the International Council of Scientific Unions. The Special Committee on Oceanic Research (SCOR) launched a major investigation of the seas, concentrating first on the Indian ocean. The Special Committee on Antarctic Research (SCAR) continued antarctic studies begun by IGY. The Special Committee for Space Research (COSPAR) similarly continued and extended cooperative studies of space initiated by IGY. The International Geophysics committee (CIG) succeeded the IGY committee in its responsibilities for data interchange and publication of the *Annals*, and initiated such programs as the World Magnetic survey, the Upper Mantle program and the International Years of the Quiet Sun (IQSY). The fields of IQSY study included magnetic fields, ionospheric physics, aurora and airglow, all radiations and charged particles in the atmosphere and nearby space, and solar activity. IQSY was scheduled for the period of sunspot minimum (1964–65), while IGY occurred during sunspot maximum. *See* SPACE EXPLORATION. (HH. O.)

INTERNATIONAL INSTITUTE OF AGRICULTURE, a clearinghouse of world agricultural information in the international sphere whose functions included the collection, analysis and publication of facts about crop and livestock production, trade, prices and related subjects "for the protection of the common interests of the farmers" of all nations. The institute was founded in Rome in May 1905. It was disbanded and its activities were transferred in 1946 to the Food and Agriculture Organization of the United Nations (*q.v.*), which superseded it.

The idea of the institute was proposed by David Lubin, a merchant of Sacramento, Calif. King Victor Emmanuel III of Italy called the first conference at Rome in 1905. The convention treaty establishing the institute was later ratified by the governments of 77 nations. The convention provided for a staff of experts to be directed by a permanent committee consisting of one delegate of each country. The institute was financed by contributions of the member nations according to the class of membership chosen.

The technical staff eventually grew to about 100 men and women of more than 30 nationalities. They assembled one of the largest

agricultural libraries in the world, housed in the building donated to the institute by the king of Italy; later a special library building was erected, aided by a grant of funds by the International Education board.

The institute published several series of journals, monographs, yearbooks and special reports in both French and English. The first attempt to make a world-wide agricultural census was begun for the years 1930 and 1940. Much of the work of the staff was done in connection with the biennial general assemblies held at Rome as well as hundreds of special meetings throughout Europe. The institute collaborated with the League of Nations, the International Labour organization and the economic conferences of 1927, 1933 and 1939, and participated in the organization of world congresses on forestry, wheat, poultry and dairying.

During World War II the international character of the institute was recognized by the belligerents and its work continued on a reduced scale. When the Food and Agriculture Organization of the United Nations was started in 1943, the member nations of the institute decided to dissolve it and turn its archives and staff over to the new organization, which was planned to cover the same field with more adequate resources. The staff was either retired or employed by the FAO, and the work of the institute terminated on July 31, 1946. The library of the institute, designated as the David Lubin Memorial library, was transferred to the FAO headquarters building in Rome, which had been provided by the Italian government. (J. C. Ms.)

INTERNATIONAL LABOUR ORGANIZATION, an official international institution that was created by the 1919 peace settlement but later became a specialized agency of the United Nations. The ILO is unique among international organizations in that the representation of each state is tripartite, including representatives of the government, workers and employers.

The ILO's chief organs are its conference, which usually meets yearly and at which all members are represented; its governing body; and the permanent secretariat, known as the International Labour office, under the direction of an appointed director-general. The headquarters of the ILO is in Geneva, Switz. Its chief forms of activity include the proposing of international treaties (known as conventions) and recommendations to governments, offering technical assistance and co-operation, making investigations, suggesting policy, compiling statistics and carrying on research and publicity. It has concerned itself with all forms of labour and social legislation and with the administration of labour laws. It has studied hours of work, wages, occupational health and safety, social security, manpower needs and the recruiting and training of workers and supervisors. It has also given attention to co-operative organizations, handicrafts and rural industries, international migration, freedom of association and trade union rights, industrial relations, workers' education, management development, productivity, employment policies, combating unemployment and underemployment, and the labour and social aspects of international competition, of technological change and of economic development.

ORIGINS AND HISTORY

During the 19th century a number of reformers urged international economic agreements by governments to minimize the hardships to workers and the dangers to peace which they saw as inherent in modern industrialization and international economic competition. In 1900 a private organization, the International Association for Labour Legislation, was established, with headquarters, known as the International Labour Office (not to be confused with the later ILO), in Basel, Switz., in 1901. It succeeded in getting a diplomatic conference in 1906 to adopt two conventions, one to limit the hours of night work of women in industry, another to prohibit the use of poisonous phosphorus in the manufacture of matches. The association's pioneering efforts set "useful procedural precedents" for the later ILO.

Labour in the Versailles Peace Treaty.—As World War I increased its demands on workers for effort in the factories and for sacrifice on the battlefields, labour spokesmen in the Allied nations asserted claims for representation at the peace conference and for a peace settlement that would enhance social and economic justice. The Russian Revolution of 1917 increased the restiveness and the demands of labour in Europe. An international trade union conference in Bern, Switz., early in 1919 demanded an "international labour parliament" with lawmaking powers, in which labour would have half the votes.

The Conference of Paris in 1919 set up a commission for international labour legislation headed by Samuel Gompers, president of the American Federation of Labor. The commission put aside the more ambitious dreams of a body with legislative authority and proposed a body with powers of recommendation to national governments for action by them, in composition a tripartite body in which half the representation would be by governments, and one-fourth each by labour and by employers. The peace conference adopted these proposals and, by inserting them in the treaty of Versailles, set up the ILO.

The ILO Between World Wars I and II.—The ILO offered far less than the European or even the U.S. labour movement had asked, but as much as they seemed likely to get. The democratic labour movements of Europe (as distinct from the Communist unions which soon were competing with them, unsuccessfully, in most countries) threw their support behind the ILO, a condition indispensable for its success.

The first International Labour conference met in Oct. 1919 in Washington, D.C. The governing body chose as the ILO's first director-general, Albert Thomas, a moderate and capable French Socialist who had been his nation's wartime minister of armaments. Under his leadership (1920–32) the ILO defined its purposes broadly, strengthened its organization, built up its staff and achieved an almost complete autonomy of policy in the League of Nations system. Upon Thomas' death, his deputy, a former British career civil servant, Harold Butler, succeeded him. When Butler resigned in 1938, John G. Winant, former Republican governor of New Hampshire and first head of the U.S. Social Security board, who had served as assistant director of the ILO in 1937, became director-general.

ILO After World War II.—In 1940 the ILO moved from Geneva, Switz., to Montreal, Que., for the duration of World War II. Actively engaged in postwar planning, it convened one international labour conference at Philadelphia, Pa., in 1944. Its "Philadelphia declaration" was a restatement of ILO aims—"poverty anywhere constitutes a danger to prosperity everywhere"—and a reaffirmation and amplification of the social-economic purposes of the Atlantic Charter. The ILO's hopes of a major role in the postwar world were hardly realized, however. It was somewhat suspect to states not members of the League of Nations because of its ties with the League. The San Francisco United Nations founding conference snubbed the ILO, despite British support, for the United States was lukewarm toward it and the Soviet Union definitely hostile. The UN charter made no mention of it, while giving broad powers to the UN Economic and Social council. The ILO became one of the specialized agencies by its agreement with the UN in 1946. The ILO kept most of its autonomy of policy and received a budgetary autonomy it had not had under the League.

In 1941 Edward J. Phelan, an Irishman who had been Butler's deputy and before that a career British civil servant, had succeeded Winant. On Phelan's retirement in 1948, David A. Morse, United States undersecretary of labour, became director-general.

Changing Emphasis.—In the period between World Wars I and II, the ILO had been primarily concerned with its research and "legislative" efforts, the attempts to define and promote proper minimum standards of labour conditions by international conventions and recommendations. In the post-World War II world, although conventions and recommendations continued important, the ILO shifted its major emphasis to the programs of technical assistance to underdeveloped areas. This emphasis, which predominated after 1949, led it to take on work of an operating character and to focus less upon the economically advanced nations of Europe and more on the underdeveloped countries of Asia, Latin America and Africa.

CONSTITUTION AND STRUCTURE

The ILO brought into official intergovernmental organization the representation of functional groups, a principle which had been applied to economic and social administration within various nations. In the International Labour conference, each member state is represented by two government delegates and (normally) one employer and one worker delegate, the two latter named by the government in consultation with "the most representative organizations of employers and workers" (where such exist) in each country. Not all delegations are complete, however.

To avoid the rule of unanimity, the ILO from the outset required only a two-thirds vote by its conference for the passage of a convention or a recommendation. The government delegates often cast the deciding votes when there were differences of opinion between the employer and worker delegates.

The conference is the supreme authority of the ILO on most policy matters, but the governing body discusses and votes the ILO budget, appoints the director-general and controls the International Labour office. Tripartite, like the conference, the governing body carried out another innovation of international representation. In the conference all nations are equal, with every delegate having a single vote. In the governing body, 10 of the government representatives must come from the 10 member states "of chief industrial importance."

Tripartism, in the 2:1:1 ratio, is firmly established in the conference and governing body. Various proposals to amend the constitution to give workers a larger representation, or to put both worker and employer delegates on a numerical par with those of government, have been rejected. Governments must be persuaded of the practical value of any proposal if it is to begin to receive implementation. The 2:1:1 ratio, however, prevails only in the phases of ILO work requiring binding votes. In conference committees and in the industrial committees (*see* below), representation of the three interests is equal. Thus the organization seeks the maximum contribution of specialized knowledge and the democratic participation of the major parties to industrial life—unions and employers—along with that of governments in its substantive work.

Two problems raised by tripartism have been troublesome because they involve fundamental differences of national political and social structure. One is the right of governments to name as employer representatives the managers of state industries or enterprises. The other is the naming of worker delegates by governments which systematically manipulate or repress labour unions within their borders.

The first issue arose when, in 1954, the U.S.S.R. and a number of Communist states rejoined the ILO. Employer representatives of other countries for the most part held that the Communist countries' employer delegates could not represent the employer interest; therefore they refused to appoint them to committees. In 1959 the conference reached a compromise which thereafter permitted the seating of some of the challenged employer delegates on committees. It satisfied neither private-enterprise employer spokesmen nor the Communist states, but continued in uneasy and experimental operation, in accordance with "equality of treatment for all members attending the conference" and the organization's universality.

Membership.—The ILO's ideal has been universality of membership. It admitted Germany as early as 1919, long before the League of Nations did. Some nations—Brazil and, for a time, Japan—remained in the ILO after quitting the League. Others became members of the ILO without joining the League or the UN. The United States remained aloof from the League but joined the ILO in 1934. After World War II the ILO admitted the German Federal Republic (West Germany). In 1961 its conference condemned the racial policies of the government of the Republic of South Africa and asked it to withdraw from the ILO "until such time as it abandoned apartheid," but South Africa refused to do so.

Post-World War II amendments made it easier to join the ILO. Members of the UN do not have automatic membership in the ILO, as did League members, but they may become members simply by filing a declaration accepting the obligations of the ILO constitution. Nonmembers of the UN must be accepted by a vote of two-thirds of the conference, including that of two-thirds of the government delegates. By 1962 the ILO had 102 members.

OPERATION OF ILO

Conventions and Recommendations.—The standard-setting process of the ILO, the major activity of its first two decades, uses the instruments of conventions (treaties) and recommendations. Member states are obliged to submit either a convention or a recommendation to the national "authority or authorities within whose competence the matter lies, for the enactment of legislation or other action" within a year or, under exceptional circumstances, 18 months. In the case of a federal state, the federal government must submit the convention or recommendation not only to the national legislature but also to the state or provincial authorities whenever it is, in whole or part, within their jurisdictions. A convention ratified by the nation's constitutional process becomes binding upon the nation, which makes periodic reports to the ILO on the measures taken to give it effect. If it is not ratified, the state undertakes to report on its "law and practice" with regard to the subject matter of the convention.

A recommendation makes it possible to offer an international standard higher than that which at a given time may seem the maximum suitable for a convention, or to offer a general principle where a binding obligation by states is not being sought. The same problem may be dealt with by both forms, the convention setting an international minimum, and the recommendation a higher norm for more advanced countries and a level of aspiration for others. By 1961 the ILO had adopted 115 conventions and 114 recommendations, constituting the *International Labour Code*. The conventions had received by mid-1963 a total of 2,730 ratifications, plus 1,339 declarations of application by governments to their nonmetropolitan territories.

Frequently states do not ratify conventions where their practice is as good as, or in most ways better than, the ILO's standards, because (1) governments and labour organizations are against enactment of any standards not so high as existing practices, or (2) in many federal states, national government does not have the constitutional power to ratify, for the conventions deal with matters wholly or partly within state or provincial authority. On the other hand, some states, out of a desire to be or to appear "advanced," have ratified many conventions but have done little to put them into practice. This was, for example, the case between World Wars I and II, with some social security conventions ratified (and codes enacted) without regard for countries' limited economic possibilities or weak administrative structures.

The ILO could not, even if it wished, try to enforce the binding ratifications. Its constitution provided that it could appoint a commission of inquiry and eventually refer complaints to the International Court of Justice, whose decision would be final. But such recourse was impractical in an international society characterized by intense national sovereignty. The only real sanction in practice is that of public opinion, aided by the examination at the conferences of the extent of ratification and implementation of conventions, appeals to governments and public opinion and the education of officials, employers and labour.

Technical Assistance.—The gap between reality and law in relation to conventions was one stimulus to the new stress on technical assistance. Between World Wars I and II, ILO technical assistance took the form chiefly of expert advice on legislative drafting and administrative procedures. With the emphasis of the UN and the United States on technical assistance to economic and social development, beginning in 1949, the ILO amplified its services to include new techniques and operational activities. Working to raise productivity and living standards in underdeveloped countries, it also sought "to ensure that social objectives are not overlooked or sacrificed to purely economic objectives."

Fields of assistance have included vocational guidance, training and rehabilitation for workers, supervisors, teachers and administrators; methods of production—industrial, agricultural and handicrafts; co-operative organization; labour-management relations and management development; workers' education;

aid in the selection, training, movement and reception of workers migrating from one country to another; employment service organization and manpower utilization surveys; as well as such older areas of ILO work as wages and hours, industrial relations, social security, labour inspection and statistical procedures.

Methods have included a heavy reliance on the use of visiting experts drawn from many countries, fellowships, study tours, seminars, the supply of equipment and worker-trainees; *e.g.*, almost 400 Yugoslav skilled workers, foremen and technicians placed for training in factories in a dozen European countries in the 1950s.

In addition to its own programs, out of its regular budget, the ILO undertook many projects under the United Nations expanded program of technical assistance. Some were undertaken together with other UN agencies; *e.g.*, the "Andean highlands" project, for which the ILO had chief responsibility and collaborated with the UN, its Food and Agriculture organization, UNESCO and the World Health organization to help raise the living standards of the Indians of the Bolivian, Ecuadorian and Peruvian Andes, and integrate them into the economic life of each nation.

Trade Union Rights and Forced Labour.—After World War II the ILO adopted its first conventions on trade union rights (1948) and on protection of the right to organize and bargain collectively (1949). This action was overshadowed by the bitter debates over charges of violation of trade union rights, made without regard to the ratification of the conventions. The lead was taken by the Communist-dominated World Federation of Trade Unions (W.F.T.U.); its complaints, laid before the Economic and Social council, were referred to the ILO. The W.F.T.U. showed great concern for union rights in countries outside the Soviet bloc but found no occasion for complaint with conditions in the Soviet Union or its satellites. This deficiency was made up by the American Federation of Labor (A.F. of L.) and (after its formation in 1949) by the International Confederation of Free Trade Unions (I.C.F.T.U.), of which the A.F. of L. was a founding member. Although concentrating its fire on the Soviet bloc governments, the I.C.F.T.U. also complained of violations of labour rights by some non-Communist governments.

In 1951 the governing body established a committee on freedom of association, which made preliminary inquiries into complaints and had the power, if it found complaints warranted, to refer them to an impartial high-level fact-finding and conciliation commission. The ILO committee had to deal largely with complaints patently of a political motivation remote from the issues ostensibly at stake (many W.F.T.U. charges), with issues of suppression of free trade unionism inherent in the whole structure of a state (many complaints against Communist governments), and with complaints against governments in developing countries for sponsoring or directing labour unions.

Even more dramatic were the charges of forced labour leveled at the Soviet Union (and later its satellites), originally by the A.F. of L. before the UN in 1947, and then by the I.C.F.T.U. In 1951 the UN and the ILO set up a joint *ad hoc* committee on forced labour which inquired into about 100 charges against 24 governments, for by then countercharges had been leveled at many states outside the Soviet bloc. Although facilities for inquiry within the Soviet world were denied by the governments involved, the committee made public evidence of forced labour on a vast scale. The world's public opinion, dulled by a generation of horrors, took only slight note. The committee's temperate recommendations for international consideration and action were reminders to a few consciences.

Regional Activities and Industrial Committees.—Two forms of the ILO's adaptation to the enormous differences in problems of different regions and of different industries were the intensification of regional activities and the use of industrial committees. The ILO prior to World War II, for all its official relations with other continents, had been essentially European in outlook and in support. The insistent claims of national self-consciousness and of economic and social development in other continents after World War II caused it to give weight to regional conferences, to establish field offices, to appoint more non-Europeans to responsible positions and to tackle problems (and to offer technical assistance) primarily, though not solely, of interest to the near east, Africa, Asia and Latin America.

From the first (1919), the ILO had had one specialized industry committee, the joint maritime commission. In this field, the ILO achieved some of its most important results. The industry itself was international in operations; its workers and employers were highly organized; governments had long been accustomed to legislating on its problems. The ILO's 25 conventions and 10 recommendations made up a comprehensive and influential international seafarers' code. After 1945 the ILO set up eight new tripartite industrial committees. Although they dealt with a wide variety of problems in major industries, none of them attained the importance of the joint maritime commission.

The International Labour Office.—The office, the secretariat of the organization (and of the conferences and the governing body) consisted in the early 1960s of more than 1,100 international civil servants, from more than 70 nations, and some experts on temporary assignments. Most of them worked in the ILO headquarters at Geneva; a number were, at any given time, in the field, all over the world. Substantial reports on subjects under consideration by conferences and committees, continuing research and statistics, publicity, a large library, technical assistance, legislative and administrative drafting, expert counsel in any field of labour and social policy are among the staff's contributions. In 1961 the ILO inaugurated an ambitious International Institute for Labour Studies at Geneva with its own endowment fund. Something of the ILO's manifold activities may be seen in its publications, whose extent can be gauged from its *Catalogue of Publications.* Among the most widely used are the monthly *International Labour Review* and the *Year Book of Labour Statistics.*

INTERNATIONAL LANGUAGE: *see* UNIVERSAL LANGUAGE.

INTERNATIONAL LAW, PRIVATE: *see* CONFLICT OF LAWS.

INTERNATIONAL LAW, PUBLIC. International law, or the law of nations, is a body of rules and principles which states consider legally binding upon them. Its origins may in part be traced to the middle ages and antiquity; but the general body of modern international law dates from the late 16th and the early 17th centuries, when it was called into being to order the relationships and conduct of the newly appearing sovereign independent states of Europe. Clearly, a system of legal precepts binding upon sovereign states needed some prior authority. The writers of the formative period of international law—particularly the greatest of them, Hugo Grotius (Huigh de Groot), whose *De jure belli et pacis* (1625) remains one of the most important books of all time —found that authority both in the much older idea of a system of natural law discoverable by reason, and in that part of Roman law, the *jus gentium* ("law of nations"), which had always been considered to be *ratio scripta* ("written reason"), and to consist in rules both generally accepted and of universal validity.

Writers have always felt the need to explain and justify the legally binding nature of international law; for the notions of state

sovereignty and the subjection of states to law do not easily ride together. When the idea of a system of natural law was unfashionable—particularly in the England of the 19th and early 20th centuries—an alternative basis of legal obligation was found by the so-called positivist school in the supposed consent of states to be bound; a consent, manifested sometimes expressly, as in a treaty, or sometimes tacitly, as in a rule of customary law. The positivists did a great service in emphasizing the importance of the study of actual state practice as a source of positive law; but their attempt to found obligation upon consent—though still echoed in innumerable judgments in English and United States courts—raised as many questions as it appeared to solve. It was never satisfactorily explained why, for example, a state which consented to a treaty and so became bound by it could not withdraw that consent at its discretion. It may well be a mistake to postulate some essential difference between international law and internal law in the matter of the basis of obligation. The notion that international law does not require a particular and special pleading to establish its legal nature has the advantage of being in accord with the factual situation. For while writers have sometimes found it convenient to deny the legal nature of international law, it is easily demonstrable that states do recognize their obligation to observe it.

The major difference between international law and internal law is not, as the layman often supposes, that international law is less consistently obeyed than internal law. It is true that much of the so-called law of war which used to be an important part of the system has in many ways proved both inadequate and irrelevant; this situation obtains for reasons which will be discussed later on. But the main body of the law between states in peacetime is probably more consistently applied and obeyed than many systems of internal law. Nor is the apparent lack of sanctions anything like so serious as the layman is apt to imagine. As J. L. Brierly put it in *The Basis of Obligation in International Law and Other Papers* (p. 54, Oxford University Press, London, 1958), "the regular observance of the international law of peace is explained only too easily; it is generally observed largely because there is little temptation to violate it, because its yoke lies easily—too easily—on the states, and also because to violate it habitually would invite reprisals and would not be in the interest of any state. But all that does not alter the fact that in spite of the vagueness of its sanctions, the law is very rarely broken."

Nevertheless, there are two important ways in which international law has less efficacy than internal laws. First, there are many areas of state activity, and these some of the most important, where the law reaches hardly at all. Thus, questions such as nationality, armament, immigration and fiscal and trade policies—all of which may vitally affect international relations—are traditionally within the untrammeled competence of the state itself to order and determine. It is true that there is a tendency of the law to feel its way gradually into these areas where formerly an anarchic sovereign discretion in each state was sanctioned by the law. Thus, until fairly recently, even the right to wage war was one which the law left to each state to exercise at its complete discretion but this is now no longer so. A serious qualification of the law that still remains, however, is the maxim that a court can exercise jurisdiction over a state only where the state has in some way consented to that jurisdiction; so that, for example, the International Court of Justice at The Hague has a compulsory jurisdiction, in the sense that a defendant state can be compelled to plead and to submit to judgment, only in a very limited sphere.

The second important difference between international and internal law is the comparative lack of international organizations and institutions. A developed system of internal law cannot be imagined without legislature, executive and judiciary. Yet, until about the middle of the 19th century, international law was virtually without institutional organizations, and thus dependent for action upon the separate governments of the states composing the family of nations. After the middle of the 19th century there was increasingly rapid development on the institutional side of international law, but 100 years later the machinery available was still far short of what is required for a mature and adequate system.

The Sources of International Law.—The term source is here used to connote "those agencies by which rules of conduct acquire the character of law by becoming objectively definite, uniform, and, above all, compulsory" (C. K. Allen, *Law in the Making*, 6th ed., p. 1, Oxford University Press, London, 1958). Obviously, every system of law must have criteria by which one can set about discovering the rule of law on a particular matter at a given time. For international law, those tests of validity have been authoritatively stated in art. 38 of the Statute of the International Court of Justice, by which it is provided:

> 1. The Court, whose function is to decide in accordance with international law such disputes as are submitted to it, shall apply:
>
> a. international conventions, whether general or particular, establishing rules expressly recognized by the contesting states;
>
> b. international custom, as evidence of a general practice accepted as law;
>
> c. the general principles of law recognized by civilized nations;
>
> d. . . . , judicial decisions and the teachings of the most highly qualified publicists of the various nations, as subsidiary means for the determination of rules of law.

By conventions is meant what are commonly called treaties. The many thousands of treaties in force now form much the greater part of the fabric of international law. This was not always so. Treaties were formerly mainly political in content: peace treaties, alliances and the like. It was not until the 19th century that the multipartite treaty began to be used for creating law between the parties. Nowadays, the multipartite lawmaking treaty is an indispensable instrument of the society of states. It must be remembered, however, that, with very few exceptions, treaties are contractual in the sense that they are only binding upon states parties to them.

The customary element in international law is prior to treaty law in the sense that the binding force of treaties themselves depends upon rules of customary law. To establish a rule of customary international law it must be shown that there exists not only a practice or habit among states, but also a recognition that the practice follows a rule legally binding on them. Customary law must accordingly be distinguished from mere usage, however well established; and from the rules of international comity, which, however well observed they may be, are recognized by states as being demanded by courtesy rather than by law. Thus, the elements necessary to establish a rule of customary law are, in the words of Judge M. O. Hudson (*Permanent Court of International Justice*, p. 609), "the concordant and recurring action of numerous states in the domain of international relations, the conception in each case that such action was enjoined by law, and the failure of other states to challenge that conception at the time."

There has been some controversy over the precise meaning of the provision in the court's statute requiring it to apply general principles of law; but there can be no doubt about its importance. One general principle common to, and necessary to, all systems of law is that the law is complete in the sense that there must be some legal answer to every legal problem. The positive aspect of this principle is neatly expressed in a well-known international arbitral award: "International law, as well as domestic law, may not contain, and generally does not contain, express rules decisive of particular cases; but the function of jurisprudence is to resolve the conflict of opposing rights and interests by applying, in default of any specific provisions of law, the corollaries of general principles, and so to find . . . the solution of the problem." (*Eastern Extension, Australasia and China Telegraph Co. Ltd., Case*, 1923).

Accordingly, international law, even where relatively lacking in detailed and elaborated rules in some of its aspects, is a complete system when seen against the back cloth of the general principles of law, which are to be collected from a study of the several internal systems and of law in general. Examples of general principles which have been assumed by tribunals to be part of international law are the principle of unjust enrichment, that he who is unjustly enriched to another's damage must make compensation; the rule called by common lawyers estoppel, that a party may not in his assertions be allowed to blow hot and cold in the same case; and the rule of *res judicata*, that a final decision by a proper tribunal disposes of a dispute once and for all.

It should not be supposed that this provision of the court's

statute was an innovation; for general principles of law have necessarily been a source since the beginnings of international law. It should be added that the general principles of law are regarded by some as being nothing more or less than the principles of natural law. At any rate, the inclusion of this source in the statute of the International Court of Justice was a rejection of extreme positivist ideas that international law rests solely upon the consent of sovereign states.

Judicial decisions are, with text writers, recognized as "subsidiary means for the determination of rules of law." Obviously there can be no rigid system of binding precedent of the kind peculiar to the common law; but argument from persuasive precedent is inevitable, for it is a natural tendency of the human mind. The International Court of Justice has shown no reluctance to refer to its own earlier decisions, nor to the awards of other international tribunals. Case law is, of course, dependent on there being a system of reports; as well as the international court's own series, there are the *International Law Reports*, published in the United Kingdom, which report not only the decisions of all international courts and tribunals but also the many decisions involving questions of international law of national courts all over the world. The transformation of international law into a case law system, which has taken place mainly since 1930, is a movement the importance of which it would be difficult to exaggerate; for it provides a resilience and a factor of growth not easily achieved in other ways.

The opinions of writers serve as evidence of what the law is, exactly as they do in other systems. Their function was well described by Justice Horace Gray in a decision of the United States supreme court on an international law question (*Paquete Habana*, 1899, *American Prize Cases*, p. 1938):

> ... where there is no treaty, and no controlling executive or legislative act or judicial decision, resort must be had to the customs and usages of civilized nations; and as evidence of these, to the words of jurists and commentators who by years of labour, research, and experience have made themselves peculiarly well acquainted with the subjects of which they treat. Such works are resorted to by judicial tribunals, not for the speculations of their authors concerning what the law ought to be, but for trustworthy evidence of what the law really is.

Relationship With the Internal Law of States.—To understand international law it is necessary to appreciate its close relationship to the internal law of states, or, as lawyers say, the municipal laws of states; for it is increasingly penetrating that sphere. Even the traditional international law, at a time when it was supposed to be a law only between states, had many rules which required the co-operation of municipal courts for their realization; for example, the very ancient rules whereby foreign sovereigns and their diplomatic representatives enjoy certain immunities from the municipal jurisdiction. But a very large part of modern international law is directly concerned with the activities of individuals which come before municipal courts. So that it is in municipal courts that a large and increasing part of international law is enforced.

One school of thought accepts that international law may be per se a part of the law of the land and that the municipal court therefore, in the appropriate case, applies international law directly. Another insists that a municipal court can only apply and enforce its own municipal law, and that the international law rule is binding only on the state itself, which must by legislation transform the precept into one of municipal law. The two approaches can on occasions lead to different results; *e.g.*, in a case involving a treaty which the government has omitted to transform into a municipal statute. But the second, or dualist, theory can hardly be applied in any case in those many countries (*e.g.*, the Republic of Ireland, France and the German Federal Republic) where it is by the constitution provided that international law is part of the law of the land.

The position before English courts is not so straightforward. There can be no doubt that they regard customary international law as part of the law of the land, for they take "judicial notice" of it; that is to say they assume that the court knows the law and does not require it to be proved by calling expert evidence, as in all cases involving foreign and external systems of law. The courts do in fact regard any relevant rule of customary international law as incorporated into the domestic law.

However, this statement must be understood subject to certain qualifications. First, English courts have tended to apply their doctrine of rigidly binding precedent even in cases involving customary international law. Thus, although the court may initially have applied the pure rule of international law, the rule may in the English jurisprudence have become fossilized just because the original decision has become a binding precedent; while the rule as it exists in the main stock of international law may have changed considerably in the course of its natural development. A notorious example is the rule by which a foreign sovereign state enjoys immunity from the jurisdiction of the municipal courts: in origin a simple and reasonable principle which, in the course of English case law, has become peculiar and technical while retaining an archaic form which some consider inappropriate to modern conditions. Secondly, it must be remembered that in England a statute is paramount law and must therefore be applied even if found to be contrary to international law (*cf. Mortensen* v. *Peters*, 14 S.L.R. 227). In such an impasse it is for parliament to get itself out of difficulties of its own creating by changing the law. The municipal court cannot help.

A treaty, even though binding upon the United Kingdom internationally, will not be applied as such by the courts. If the implementation of the treaty requires a change in the law it is for parliament to make that change by statute. The reason for this rule is said to be that, since the treatymaking power is a prerogative power, it would, if the treaty were binding directly on the courts, amount to a power to legislate without parliament. The position is quite different for example in the United States, where treaties are binding on the courts even if in conflict with state laws or previous federal laws; on the other hand, a subsequent federal statute will overrule a previous treaty.

The Sphere of Operation.—Up to the end of the 19th century and even later, international law was mainly if not entirely a law governing the conduct of sovereign states. Theorists tended to erect this fact into a principle, and it used to be asserted, therefore, that international law could not bind or confer rights upon individuals, or upon entities other than sovereign states. But in truth there never was anything inherent in the law to prevent it applying to individuals. Indeed, as we have already seen, municipal courts have constantly found themselves compelled to take account of rules of international law affecting individuals appearing in cases before them. Developments during the 20th century have long outstripped the old orthodoxies. In 1928, the Permanent Court of International Justice recognized, in the case concerning the *Jurisdiction of the Courts of Danzig* (PCIJ, series B, no. 15) that states may expressly grant rights directly to individuals by treaty if they wish to do so, and that such rights may validly exist and be enforceable even though they have not been incorporated into the municipal law. In 1949, the International Court of Justice, in its opinion on the *Reparation for Injuries Suffered in the Service of the United Nations* (ICJ Reports, 1949, p. 179), expressly rejected the view that only states can be the subjects of international law. And, of course, the laws of war were always based on the assumption that their precepts were binding not only upon sovereign states but also upon the individuals who compose them. In its judgment of Sept. 30, 1946, the Nürnberg International tribunal said this:

> It was submitted that international law is concerned with the actions of sovereign States, and provides no punishment for individuals; and further that where the act in question is an act of State, those who carry it out are not personally responsible, but are protected by the doctrine of the sovereignty of the State. In the opinion of the Tribunal, both these submissions must be rejected. . . . Crimes against international law are committed by men, not by abstract entities, and only by punishing individuals who commit such crimes can the provisions of international law be enforced.

All this is not to say of course that some parts of the law—and particularly those which developed in the 19th century—are not still coloured by the old orthodoxies. For example, the influence of dualist doctrine is still to be seen in the so-called rule of nationality of claims, by which it is assumed that a wrong to

an individual committed in a foreign state is a wrong not to him but to his own state, and that there is no redress unless his own state takes up the claim, and, moreover, is qualified to do so by reason of his having been its national both at the time of the injury and continuously until the claim is brought. This cumbrous and unrealistic procedure is being changed only slowly into something more apt to the doing of justice.

Codification.—Since the middle of the 19th century it has often been suggested that international law would be strengthened by codification, on the grounds that a code would add certainty and precision to the law, besides offering an opportunity for the completion of the system. While there can be no doubt that the movement has been a salutary one, with considerable achievements to its credit, it has only been realized slowly that codification presents peculiar difficulties in the international sphere. A codification in the strict sense—*i.e.*, where existing law is put into written form but the substance remains unchanged—is, except perhaps in a very few restricted fields, practically impossible, because any attempted codification must involve the resolution of differing opinions about what the law is; so that some changes in the law in the course of codification are unavoidable. This process presents no special difficulty in an internal system where there is a legislature competent not only to promulgate the new code with authority but also to abrogate the former sources and understandings of the law. But in international law there is no legislative process as yet available. The nearest approach to it is the multilateral treaty; which, however, is still only binding on the parties to it. Consequently, unless the treaty becomes universally accepted, the former customary sources of the law remain valid for those who are not parties to the treaty. Thus it may be possible to argue that the former customary law remains in existence as the general law, and that the codification is a novel law binding only those who have subscribed. Hence, a codification attempted at the wrong moment may easily complicate rather than clarify the law.

These and other difficulties were demonstrated by the disappointing results of the Hague Codification conference of 1930 when, in spite of preparatory work of unexampled thoroughness, the conference failed to reach any agreement on two major topics of the law and produced only minor, and for the most part still unratified, conventions on a third.

A great step forward, however, was taken in the charter of the United Nations, which required the general assembly to initiate studies and make recommendations for "encouraging the progressive development of international law and its codification" (art. 13), thus recognizing that codification and development of the law are in practice inseparable companions. To carry out this task an International Law commission of experts was established in 1947 and began its studies in 1949. Its method has been to study certain major topics of the law and to report the results of its labours to the general assembly in the form of draft conventions with comment. It is then for the general assembly to decide whether the time is opportune for a diplomatic conference to use the work as a basis for an actual codifying convention. But in any case the reports of the commission and the materials they collect and publish have themselves enriched the law, thus demonstrating the force of Sir Cecil Hurst's plea for codification in the form of restatements by technical experts which might be expected to achieve the inherent authority of accurate and persuasive scholarship (see *Grotius Society Transactions*, 1946). In the first ten years of its working life, the commission produced reports on such important topics as arbitral procedure, diplomatic immunities, state responsibility and offenses against peace and security.

In its final report on the very important question of the various aspects of the law of the sea the commission recommended the calling of a general diplomatic conference. Accordingly, the representatives of 86 countries met at the Geneva Conference on the Law of the Sea in 1958. The conference failed, not unexpectedly, to agree on the crucial question of the width of territorial waters: a question which nicely illustrated the difficulty of maintaining a distinction between the question of what the law is and the question of what it might become. Some countries were doubtless still jockeying for position in the controversy and were not at that moment wishing to reach a final agreement. On other topics of maritime law, however, the conference was a very considerable success, for it achieved very wide agreement on four draft conventions ranging over almost the entire field of maritime law, comprising in all 106 articles, dealing with the territorial sea and contiguous zone, the high seas, fishing and conservation of resources on the high seas and the continental shelf. The draft conventions were of course subject to ratification before becoming binding upon states. The Geneva experiment was a very great advance over earlier attempts at development and codification by treaty and probably showed an increasing awareness in governments of the importance of international law and the urgent need for its development.

International Organizations.—As has been already noticed, there were in quite recent times no international organs of government and administration. International law could only function through the agency of the governments of the separate states. Thus, for example, new states were admitted—and indeed still are admitted—into the international comity of nations by the process of independent recognition by each separate state. It is true, of course, that there are legal rules governing various aspects of recognition; but the act of recognition is still a function of the states and not of an international institution. Again, the claims of individuals or corporations for reparation for international wrongs such as denial of justice have to be adopted and preferred by the government of their national state before they become viable in the international sphere. Until after World War I, the final sanction of the law was accepted as being the rough and ready one of various forms and degrees of self-help by states themselves, including ultimately war.

Some international institutions began to appear, however, in restricted and mainly technical fields in the 19th century. The first was the International Telegraph union of 1865, followed by the Universal Postal union in 1874, the Copyright union in 1886, the International Institute of Agriculture in 1905 and the Radiotelegraph union in 1906.

This development of international institutions was greatly accelerated after World War I by the establishment of the League of Nations with its many associated agencies, including two important ones which have with some changes, survived World War II, namely the International Court and the International Labour organization. The movement gathered pace again at the close of World War II with the establishment of the United Nations and its 12 specialized agencies, and the creation of numerous intergovernmental organizations exercising functions bearing on the development or administration of international law. Thus the middle of the 20th century saw the emergence of a large number of international agencies, some well-nigh universal, some regional and many of them now an indispensable part of the daily working of international society; *e.g.*, the International Civil Aviation organization, the World Health organization, the United Nations Educational, Scientific and Cultural organization, the Food and Agriculture organization, the International Monetary fund and the Bank for International Settlements.

These bodies are creatures not of a particular municipal law but of international law. The International Court has given its opinion that the United Nations itself is a person in the law in the sense that it can even bring certain kinds of claims on behalf of individuals against a state. The legal problems which are common to international organizations in general, such as questions of membership, voting powers and procedures, and relations with other organizations, with states and with individuals, were, by the middle of the 20th century, being welded into a systematic legal discipline comparable with the constitutional law of a state.

Important, however, as this emergence of an international constitutional law undoubtedly is, its significance clearly depends in the long run on the success or failure of that central part of it which is concerned with the problem of war; for a system of law fails in its primary function if it fails to regulate the use of physical force within the society it purports to govern.

International Law and War.—The founding fathers of mod-

ern international law had no doubt that the control of war must be the primary function of the system. Therefore they not only devised rules governing the conduct and methods of warfare—the so-called *temperamenta*—but also attempted to distinguish between wars which were just and lawful and those which were unjust and therefore unlawful. This attempt, however, could be of little practical significance in a society in which there was no international authority to make the determination one way or another. Consequently, from the 18th to the early 19th century, international law abandoned the attempt to distinguish between wars and followed the cynical maxim that "war is no illegality." War, which might therefore be made at the absolute discretion of each sovereign state strong enough to wage it or desperate enough to risk it, suspended the law of peace between the belligerents and brought into operation the rules of war intended in some measure to mitigate its severities and to protect civilian lives and property. Between the belligerents and neutrals there came into operation a highly sophisticated law of neutrality. This traditional law was codified, though not without ambiguity, at the two Hague peace conferences of 1899 and 1907. It is important to remember therefore, that during much of its existence, international law made no practical attempt to control the use of war as an instrument of policy.

World War I demonstrated the need not merely to attempt to control the conduct of war, but to prevent it; both on account of the increasingly devastating scale of modern warfare and also because even the old rules governing its conduct, except for certain fundamental principles stemming from the ordinary rules of humanity, were being rendered constantly obsolete or irrelevant as a result of the application of modern science to the methods of warfare. The rules tended always to be more appropriate to the last war than the present one.

The 20th century has therefore seen a return in a new form to the classical attempt to distinguish between the just and the unjust war: first in the League of Nations covenant, then more generally in the still important and binding general treaty for the renunciation of war of 1928, sometimes known as the Peace Pact of Paris, or the Kellogg-Briand pact. This was a well-nigh universal treaty in which states renounced war as an instrument of national policy and undertook to settle their disputes by pacific means, thus making all wars illegal except those waged in self-defense or against a state that had already violated the treaty by an illegal resort to war. It was this instrument which formed the legal basis for the abandonment of formal neutrality by the United States in the early stages of World War II and for her assistance to the Allies before she herself became belligerent. In 1946 there was added the charter and structure of the United Nations, in which members undertook to "refrain in their international relations from the threat or use of force against the territorial integrity or political independence of any state. . . ." (ch. 1, art. 2, sec. 4).

Conclusions.—The experience of two world wars, the failure of the League of Nations experiment and the unforeseen difficulties and frustrations of the United Nations resulted in a prevailing temper of disillusionment which contrasted strongly with the optimism of the late 19th century. Yet it is true that the 20th century has seen an unprecedented and rapid development of the main body of international law which gathered even increased momentum after the close of World War II. There is a sense in which this development was inevitable. The industrial revolution and then the technological revolution forced states closer together and greatly increased the importance and variety of crossfrontier relationships in trade, communications and culture. Though political theory continued to describe states in terms of sovereign independence, the most important fact about them became their interdependence. All this was bound to produce great changes in the law. For law is not created by the speculations of jurists, or even by the desire of peoples for it, but by their real needs and by the pressures of events. Accordingly, if the international law of the mid-20th century is compared with the international law of the latter part of the 19th century great differences are found. The first and most immediately striking is the increase in the sheer bulk of it. Some idea of this change can be gained by comparing the slim volume of a little more than 200 pages which Sir Henry Maine found sufficient to cover the subject in his Cambridge lectures of the 1880s, with the 2,000 or more pages of a modern basic text book such as L. F. L. Oppenheim's *International Law*, edited by H. Lauterpacht (vol. i, 8th ed., 1955; vol. ii, 7th ed., 1952). But the most important difference is the change in content. At the end of the 19th century and even perhaps after the end of World War I, it was still necessary to define international law in the traditional terms of a law to order the relations of states among themselves and to delimit the territorial spheres within which their respective sovereign and independent authorities might properly be exercised. As Sir Alfred Zimmern said, in a telling criticism of it, "modern international law was developed as a means for regulating external contacts rather than as the expression of the life of a true society" (*The League of Nations and the Rule of Law*, pp. 98–99, The Macmillan Company, New York and London, 1939). And indeed it was to be expected that a law coeval with the emergence of the nation state should have been much influenced by doctrines of the fundamental rights of states, so that much of the traditional law was concerned with aspects of state separateness and independence, rather than with the problems of an international society. But by the middle of the 20th century this was no longer the position. The proliferation of modern treaty law and relationships, the development of international organizations, the increasing concern of the law with the protection of fundamental human rights of the individual even as against his own state, the necessity for detailed international regulation of technological developments such as international civil aviation: all these factors resulted in a profound transformation of the nature and content of the law which is admirably summarized by Wilfred Jenks:

". . . . . the emphasis of the law is increasingly shifting from the formal structure of the relationships between States and the delimitation of their jurisdiction to the development of substantive rules on matters of common concern vital to the growth of an international community and to the individual well-being of the citizens of its member States. We shall also find that as the result of this change of emphasis the subject-matter of the law increasingly includes cross-frontier relationships of individuals, or organizations, and corporate bodies which call for appropriate legal regulation on an international basis, problems of economic and technological interdependence requiring the regulation on the basis of common rules of matters which do not *per se* involve inter-State relations in any real sense, and rights designed to provide the individual, and in some cases organizations, with a measure of protection against the individual member States of the international community. This international community, which is still far from having attained any political or moral unity and is always liable to be torn asunder by disruptive forces, continues to be organized on the basis of States, but its law has long since ceased to be merely, and is rapidly ceasing to be primarily, a law between States." (C. W. Jenks, *The Common Law of Mankind*, p. 17, Stevens and Sons, London, and Frederick A. Praeger, Inc., New York, 1958).

The attention of the reader is especially drawn to the following articles: Arbitration, International; Conflict of Laws; Hague Conferences; International Court of Justice; International Labour Organization; Laws of War; League of Nations; Neutrality; Sanction and Guarantee; Treaty; United Nations. *See* also references under "International Law, Public" in the Index.

INTERNATIONAL MONETARY FUND, a specialized agency affiliated with the United Nations, designed to stabilize international monetary exchange rates. Together with the International Bank for Reconstruction and Development (*see* Bank for Reconstruction and Development, International) its articles of agreement were signed, after considerable prior negotiation, at Bretton Woods, N.H., in July 1944. Ratification and appropriation of funds by national governments enabled the fund to be constituted in March 1946. Initial exchange values of member currencies were accepted at the rates then current. The fund

opened in March 1947 and made its first transactions in May.

Organization.—Operating funds are subscribed by member governments. Each member has a quota, of which an amount equal either to 25% of the quota or 10% of the member's holdings of gold and U.S. dollars, whichever is smaller, is subscribed in gold and the remainder in national currency.

The fund was designed to stabilize exchange rates by assisting members over temporary difficulties in their international balances of payments. It does so partly by consultation and technical advice, but also by allowing members to purchase from it with their own national currencies the gold or foreign exchange they need. In principle not more than 25% of the member's quota may be purchased in any one year, but in an emergency this limit may be, and often is, waived. Not more than 125% of the quota may be purchased in all. Charges begin at ½% for the first 25% for the first year, rising by ½% for each additional 25% for each additional year, with a limit of 5%. Members may arrange stand-by credits to use as and if necessary. If demands for any currency outrun the fund's resources it may be declared scarce and rationed. Members may then impose discriminatory exchange controls against it. Members are required to repurchase the excess of their own currencies over their quotas within an agreed period (three to five years) and as their balances improve.

Members agree not to alter the exchange value of their currencies (except once by not more than 10%) without prior agreement by the fund. In 1949 Britain and many other countries secured such agreement, as did France in 1957 and other countries at different periods.

Members are pledged to the ultimate elimination of exchange control and multiple exchange rates. They must consult annually with the fund on both and it works with them toward greater freedom and uniformity of exchange rates. Such consultations offer opportunities for technical advice and assistance toward currency stabilization and the freeing of exchange transactions. Staff members also frequently visit member countries to consult with national monetary agencies.

The fund has no power to dictate national monetary policies. By providing technical assistance when asked and facilities to acquire needed reserves in emergencies, it may moderate exchange crises and minimize currency instability, but it had not by the early 1960s been able to get rid of exchange restrictions.

Policy is determined by a board of governors representing each member government. Governors cast votes weighted according to the quotas subscribed by members, ranging in the late 1950s from 255 votes for Panama to 27,750 for the United States. The executive directors meet frequently. Five, representing the countries with the largest quotas (the United States, United Kingdom, China, France and India), are appointed; the others are elected by the other members. The managing director and his staff are responsible for actual operations.

Transactions.—After years of relative inactivity, the number and amount of the fund's transactions increased sharply during the Suez crisis in 1956–57. In the organization's first ten years, ending April 30, 1957, total purchases amounted to $2,350,000,000 of which $1,114,000,000 were made in 1956–57. Another $1,212,000,000 was earmarked under stand-by arrangements in that year. Most purchases were of U.S. dollars, but there were also small purchases of German marks and Dutch guilders, as in earlier years there had been of sterling, Belgian francs and Canadian dollars. Not all stand-by arrangements were used. Up until 1958 repurchases of their national currencies by members were less than new purchases of dollars. Some national quotas were increased and there was discussion in the late 1950s of the need for a general increase to enlarge the fund's resources. It was widely recognized that the fund's action in making available large amounts of internationally acceptable currencies had eased the strain on national balances in the Suez crisis.

INTERNATIONAL ORGANIZATIONS, institutions drawing their membership from two or more states, and maintaining arrangements and facilities designed to promote periodic or continuous activities by their members.

The 20th-century trend toward the creation of international organizations on a wide scale was essentially a product of circumstances stemming from advances in the technology of communication, transportation and warfare, and from the growth of industrialism. These developments gave rise to a sense of interdependence among the peoples of the world, thereby stimulating recognition of the need for systematic international co-operation to avoid the dangers, curb the evils, solve the problems and exploit the opportunities which confront the society of nations. These same developments also gave an unprecedented air of feasibility to the project of creating and operating organizations on a world-wide scale. Such institutions vary greatly in geographical scope, ranging from regional organizations to universal bodies embracing virtually the whole world. Some are concerned only with single and relatively narrow problems, while others, *e.g.*, the United Nations, deal with a great variety of substantive matters. Finally, international organizations may be designated as either intergovernmental or nongovernmental agencies.

Nongovernmental Organizations.—Typically, international nongovernmental organizations are associations of private groups organized separately within various states, although some are based upon the membership of individuals. The distinction between the intergovernmental and nongovernmental types is not always clear cut. Many organizations are mixed in composition. The International Labour organization, for instance, while fundamentally an intergovernmental body, included in the 20th century spokesmen for national employers' and workers' associations along with official representatives of governments as voting delegates to the sessions of its major organs.

On the nongovernmental level, groups were organized for such purposes as the international exchange of knowledge, the promotion of religious and humanitarian causes and the development of parallel or co-ordinated practices among nations in particular areas of activity. Nongovernmental organizations also in many instances promoted the creation of intergovernmental agencies in the fields of their concern, and advised and assisted the latter bodies in their operations. While most nongovernmental organizations were designed to stimulate co-operative achievement of practical results in rather specialized fields of endeavour, some reflected a desire to cultivate internationalism as a value in itself, promoting friendly contact and habits of international co-operation as a contribution to the creation of an orderly and peaceful world.

Intergovernmental Organizations.—The intergovernmental category includes those established by agreement among governments, and maintained by states, which exercise their membership functions through governmental representatives. Public international organizations, of the mid-20th century, although less numerous than the nongovernmental agencies, generally attracted greater attention and had more adequate financial support. Their creation reflected a disposition to seek new techniques and improved facilities for coping with the tasks of government under the increasingly complex circumstances of the modern era. In particular, the ancient moral ideal of world peace and the urgent practical requirement of avoiding the devastating results of modern war produced an emphasis upon the peace-preserving function of intergovernmental organizations. Although governments formed international institutions to deal with a variety of highly technical problems, there was at mid-century a growing tendency to express the formal purpose of these agencies in terms of their potential service to international peace and security.

Accelerated 20th-Century Development.—The association of the tendency to create international organizations with the development of the complexities of modern interdependence is dramatically illustrated by statistical analysis. According to a 1957 report by the Union of International Associations, *Les 1,978 or-*

ganisations internationales fondées depuis le Congrès de Vienne ("The 1,978 international organizations founded since the Congress of Vienna"), only a handful of international organizations in existence in the late 1930s were formed before 1850; approximately 10% were established before 1900; and about 90% of the organizing activity was concentrated in the period, 1900–56. The accelerating pace of the movement was particularly notable in the decade following World War II, when more than 600 nongovernmental and over 80 official organizations were formed.

In the early 1960s there were more than 1,100 international organizations. This number included more than 130 intergovernmental agencies, of which the most notable were the United Nations, the various specialized agencies affiliated with the United Nations, and such regional organizations as the European Coal and Steel Community, the North Atlantic Treaty organization and the Organization of American States. The variety of subjects with which intergovernmental organizations were concerned was indicated by such names as the Central Commission for the Navigation of the Rhine, the International Tin Study group, the International Patent institute, the European Organization for Nuclear Research and the International Whaling commission. Nongovernmental organizations were listed by the Union of International Associations under 19 headings ranging from "Religion and Moral Improvement" to "Sport and Recreation." The largest concentrations of private international organizations fell under "Labour and Professions, Employers, Trade Unions," "Commerce and Industry" and "Medicine, General and Mental Health."

The first half of the 20th century was marked not only by the rapid multiplication of international organizations, both private and public, but also by efforts to create a pattern of orderly relationships among them. The Union of International Associations, founded at Brussels, Belg., in 1907, was an early co-ordinating body. The League of Nations, created after World War I, provided a focal point for intergovernmental organizations and also for the growing network of nongovernmental agencies. Following World War II, the United Nations became a kind of "roof organization" for the major enterprises in systematic international cooperation. In accordance with art. 57 and 63 of its charter, the UN entered into co-ordinating agreements with intergovernmental agencies operating in economic, social, cultural, educational, health and related fields. In the second half of the 20th century the roster of specialized agencies affiliated with the United Nations included: Inter-Governmental Maritime Consultative organization (IMCO); International Labour organization (ILO); United Nations Educational, Scientific and Cultural organization (UNESCO); Food and Agriculture organization (FAO); International Civil Aviation organization (ICAO); International Monetary fund; International Bank for Reconstruction and Development (World Bank); World Health organization (WHO); International Telecommunication union (ITU); Universal Postal union (UPU); World Meteorological organization (WMO); International Atomic Energy agency; and the International Finance corporation. The Economic and Social council of the United Nations, acting under art. 71 of the charter, also maintained a consultative relationship with nearly 300 nongovernmental organizations, virtually all international in scope.

The United Nations did not, however, become, nor was it intended to become, a central authority with power to control the operations of other international organizations. A great number of international agencies of all types remained outside the institutional family over which the United Nations presided. Nevertheless, the United Nations was responsible for the closest approach made to the development of a system within which the work of the great mass of international organizations might be harmonized and co-ordinated. *See* also AMERICAN STATES, ORGANIZATION OF; BANK FOR RECONSTRUCTION AND DEVELOPMENT, INTERNATIONAL; BENELUX; CENTRAL AMERICAN FEDERATION; FOOD AND AGRICULTURE ORGANIZATION; INTERNATIONAL COURT OF JUSTICE; INTERNATIONAL INSTITUTE OF AGRICULTURE; INTERNATIONAL LABOUR ORGANIZATION; INTERNATIONAL MONETARY FUND; INTERNATIONAL REFUGEE ORGANIZATION; INTERNATIONAL TRADE ASSOCIATIONS AND CONGRESSES; NORTH ATLANTIC TREATY ORGANIZATION; PAN-AMERICAN CONFERENCES; PAN-EUROPEAN MOVEMENT; RED CROSS; SOUTHEAST ASIA TREATY ORGANIZATION; UNITED NATIONS; UNITED NATIONS EDUCATIONAL, SCIENTIFIC AND CULTURAL ORGANIZATION; UNITED NATIONS RELIEF AND REHABILITATION ADMINISTRATION; POSTAL SERVICES; WARSAW TREATY ORGANIZATION; WORLD GOVERNMENT MOVEMENTS; WORLD HEALTH ORGANIZATION.

INTERNATIONAL PAYMENTS. The main difference in the settlement of international and domestic transactions is the existence of different currencies. This, however, is not a serious obstacle as long as the currencies are freely convertible into each other, and into gold. When, for example, British importers can buy United States dollars from their banks for sterling and U.S. exporters can sell sterling to their banks for dollars, it is immaterial in what currency the transaction is settled. Banks trading in foreign exchange normally keep balances in the appropriate currencies with their branches, agents or correspondents abroad in order to facilitate the clearing process. But whereas interbank credits or debits outstanding can be settled internally in terms of local currency, they are settled internationally either from accumulated balances of foreign exchange, or by loans from the creditor to the debtor, or by drawings on the International Monetary fund (*q.v.*) or by movements of gold. Whenever this process is multilateral rather than bilateral, it provides an additional advantage. For if, in terms of the total annual turnover of transactions between them, England is in debit to the United States and in surplus with the colonies and the latter in surplus with the United States but in debit to England, there is no net change in the foreign-exchange position of the areas concerned if the various credits and debits exactly cancel out. In practice, however, it does not work out so smoothly; there always have been considerable fluctuations in net credit and debit positions within any given year as well as between years. The way in which a country balances its international accounts is one of the most important problems of its balance of payments.

BALANCE OF PAYMENTS

The balance of payments is a systematic record of all economic transactions during a given period between residents (including the government) of one country and residents (including the governments) of other countries, referred to for convenience as foreigners. The transactions are presented in the form of double-entry bookkeeping with credit entries balanced on the debit side, and vice versa. The balance of payments of a country thus necessarily balances. There can be no surplus or deficit in a country's balance of payments as a whole.

This accounting equality of a country's total credits (receipts) and total debits (payments) may be readily illustrated. The balance of payments of the United States, for example, records the various ways in which dollars are made available to foreigners through U.S. imports, tourists' expenditures, military expenditures, donations, foreign lending activities and so forth. These expenditures are shown on the debit (payments) side of the balance. The credit (receipts) side indicates the various uses to which foreigners put their dollars, such as paying for U.S. exports, servicing of debts to the United States and the like. If foreign countries do not spend all the dollars made available to them during a given period to obtain goods and services from the United States, the balance of payments will show on the credit (receipts) side an increase of foreign-held dollar balances, foreign purchases of U.S. securities, gold exports from the United States or some similar item. If, on the other hand, the dollars made available by the United States are insufficient to pay for the exports of U.S. goods and services, additional dollars can be obtained only by liquidation of foreign holdings in the United States, by gold imports into the

United States and by similar operations which would necessarily be recorded on the payments side. This must mean that for any period the receipts measured in dollars are equal to the payments measured in dollars when all the receipts and payments are included. But this equality of payments and receipts in the formal "balance sheet" conceals the reasons why countries are so concerned with their balances of payments. Hence, not whether the accounts are balanced but how they are balanced is the important question.

Standard Schedule for Reporting Balance of Payments to International Monetary Fund

Current transactions. Reporting country——Period covered——Currency——Unit——Exchange rate: U.S. $ per——	Credit (receipts)	Debit (payments)	Net credit (+) or debit (−)	Movement of capital and monetary gold. Reporting country——Period covered——Currency——Unit——Exchange rate. U.S. $ per——	Net movement, increasing (+) or decreasing (−)		
					Assets	Liabilities	Net assets
Item				Item			
A. Goods and Services				C. Capital and Monetary Gold			
1. Merchandise: exports f.o.b.				Private, excluding banks			
Merchandise: imports f.o.b.				11. Long-term liabilities			
2. Nonmonetary gold				Direct investment (in country)			
3. Foreign travel: credit				Transactions in securities			
Foreign travel: debit				12. Short-term liabilities			
4. Transportation: credit				13. Long-term assets			
Transportation: debit				Direct investment abroad			
5. Insurance: credit				New foreign security issues			
Insurance: debit				Retirement of foreign securities			
6. Investment income: credit				Transactions in outstanding securities			
Investment income: debit				14. Short-term assets			
7. Government, n.i.e.: credit							
Government, n.i.e.: debit				Official and Banking Institutions			
8. Miscellaneous: credit				15. Long-term liabilities			
Miscellaneous: debit				16. Short-term liabilities			
				To foreign officials and banks			
				To other foreigners			
B. Donations				17. Long-term assets			
9. Private				Official loans extended			
10. Official				Official repayments			
Total (1 through 9)				Other			
Total (1 through 10)				18. Short-term assets			
				Government			
				Other			
Net errors and omissions				19. Monetary gold			

Operations Entering Into the Balance.—Countries are greatly concerned about the types of transactions giving rise to the receipts and payments of foreign exchange and how these compare in size with one another. The accompanying table comprises all the items in the standard schedule for reporting a country's balance of payments to the International Monetary fund (IMF). It is divided into two major sections: the current account and the capital account.

The current account records all transactions other than those representing changes in the international creditor-debtor position of the reporting country and in its monetary gold holdings. It includes two distinct types of transactions: items 1 through 8, which refer to transfers of goods and services, and items 9 and 10, which cover private and official donations. The credit entries under items 1 through 8 correspond to goods and services supplied, the debit entries to goods and services received. Credits under items 9 and 10 show donations received by the country; debits show donations made.

The capital account records all transactions representing changes in the international creditor-debtor position of the reporting country and in its holdings of gold and other monetary reserves. It does not include valuation changes (*e.g.*, changes in the market values of securities, or revaluations of assets and liabilities because of exchange-rate adjustments) since these are not transactions. The capital movements shown do not, therefore, necessarily reflect the total change in the creditor-debtor position of the reporting country during the given period. In order to present a maximum of information compactly, the capital account is shown in terms of net changes—increases or decreases—in assets and liabilities. Increases in assets and decreases in liabilities indicate an outflow of capital (a debit); decreases in assets and increases in liabilities indicate an inflow of capital (a credit). The capital account is divided into a private sector (items 11 to 14) and an official sector (items 15 to 19).

Since economic transactions included in the balance of payments involve directly or indirectly two entries—a debit and a credit—errors and omissions apart, any net balance on account of goods, services and donations taken together is matched by an equal balance with opposite sign on capital account. Because some transactions may be inaccurately recorded or not recorded at all, the "errors and omissions" item is included to bring the statement into balance (*see* table).

Various Concepts of Surplus or Deficit.—To speak of a surplus or deficit in the balance of payments would appear to be a contradiction in terms. Yet much of the discussion of international economic problems following World War II concerned certain "deficits" of the war-damaged countries and the underdeveloped areas. These problems, in part, revolved about whether certain segments of a country's balance of payments were in balance or whether they were in surplus or deficit by some amount.

The discussion sometimes ran in terms of the "trade balance"; *i.e.*, the net credit or debit of merchandise trade. While this is an important segment of the balance of payments, it may have very little significance by itself. An import surplus may be matched by net sales of services that are closely similar in their economic implications to sales of goods. There would then be no deficit in goods and services as a whole and this balance is a broader and more significant measure than is trade alone. Similarly, an export surplus may be reinforced by net sales of services, increasing the surplus in goods and services as a whole.

Often the balance of goods and services has been discussed as if it were the balance on current account. The current account as a whole has always had a basic importance since it is the counterpart of the capital account. A nation with a deficit on total current account is *ipso facto* decreasing its capital assets abroad (including gold) or increasing its capital liabilities to foreigners. A nation with a current-account surplus is gaining foreign assets or reducing its foreign liabilities. Manifestly, a deficit or surplus on current account may be of crucial importance to a country. However, in addition to the goods and services that are sold to foreigners, there are many transactions for which no payment is made. Governments that extend grants, individuals who send goods or money to families or friends abroad, and institutions that provide charity are all engaged in such transactions. The goods, services and capital items that pass in these transactions without payment are all entered in the balance of payments as if payment were made for them. They are then simply offset by contra-entries under "donations" (which may be voluntary, automatic or semiforced) to show that, in fact, payment was not required. In many instances, to state that a country financed by foreign grants had no deficit to be met is a patent contradiction. Accordingly, while the full current account (including donations) is useful in revealing the factors that have altered the international capital position of a country, it is a seriously defective measure of balance-of-payments deficit or surplus from the standpoint of exchange problems.

Even if official donations are eliminated from the current account in arriving at a figure for deficit or surplus, the result may still be misleading as an indication of the exchange problem involved. A deficit in the balance of goods and services, for example, is not necessarily an indication of pressure on a country's exchange rate. It may be matched by an inflow of investment capital which strengthens the immediate exchange position and builds up a country's future exporting capacity. Similarly, a surplus in the balance of goods and services may be no indication of a strong exchange position. It may reflect the efforts of a country

to pay reparations or to meet other fixed obligations abroad.

It is regrettable that in public discussions a deficit in the balance of trade is referred to as an "unfavourable trade balance" and a surplus as a "favourable trade balance." The notion that it is vitally important for a country to have an excess of exports over imports was stated as far back as the 14th century. A country that exports more commodities than it imports, so the argument runs, would receive the difference in gold and silver. This was regarded as a "favourable balance" because, for a country with no gold or silver mines, it was the only way to increase its stock of the precious metals. But the grounds on which early writers based their beliefs in the desirability of an indefinite accumulation of the precious metals were for the most part erroneous. The mercantilists of the 16th, 17th and 18th centuries, for example, regarded any gain in the precious metals as a gain in economic power and prosperity. (*See* MERCANTILE SYSTEM.) Clearly, from the welfare point of view, it is goods and services that account for the economic advantages derived from foreign trade. Money is predominantly a mechanism of foreign commerce. Just as it is impossible for a country to maintain indefinitely an excess of exports over imports unless it is willing continuously to accumulate gold, invest abroad or give its goods away, so it is impossible for a country to maintain indefinitely an excess of imports over exports unless it is able continuously to obtain foreign exchange from the export of gold, from grants or investments abroad, or to default.

The terms "favourable" or "unfavourable" trade balance, when not wholly invalid, are subject to such grave limitations that they are rejected in modern treatments of the subject and are replaced by such terms as "active" and "passive," or "positive" and "negative," trade balance. Other terms used for the same phenomena are "export surplus" and "import surplus," or "credit" balance and "debit" balance. The more important item, net total on current account, is often designated by the terms "surplus" or "deficit" in a country's balance of current payments. The value of the net outflow of gold plus net increases in foreign holdings of a country's short-term balances has most frequently been used as a measure of a country's balance-of-payments deficit.

BRITISH BALANCE OF PAYMENTS

Britain has had a deficit in merchandise trade since before the Napoleonic Wars. Before World War II it had been able to pay for its imports of food and raw materials largely with earnings from foreign investments built up over generations, and from services. The postwar balance-of-payments difficulties, however, which in some respects were typical of those of western Europe, were not of late origin. World War II merely hastened a great structural change in Britain's trade relations which had been going on since well before World War I.

Before World War I.—During the nation's great period of expansion—from 1780 to 1913—conditions favoured the import balance appropriate for Britain's creditor status. Its position as a pioneer in industrial development, with no tariffs or quota restrictions from 1860 to 1914, the complementary exchange of its manufactures for food and raw materials, general political stability, the large increase in overseas investment, free or "untied" lending and stable world currencies all contributed to the relatively smooth multilateral adjustment of the British balance of payments. A fortuitous historical circumstance aided this adjustment process: Britain was able to invest much of its excess savings abroad whenever plans to invest at home declined relative to the level of total savings. But even before World War I, as Germany, the United States and Japan industrialized, world trade increased; Britain's export industries, however, were unable to keep pace with the manufactured products of the expanding industrial nations. Between 1870 and the start of World War I, world production of manufactures increased fourfold, but world trade in manufactures was a decreasing fraction of total production. In the 1870s one-third entered into international trade, in 1913 one-fifth. Nevertheless, the absolute volume of world trade in manufactures increased threefold between 1880 and 1913, and that of Britain also increased considerably although Britain's relative share of world trade declined. This trade expansion assisted the equilibration of Britain's external accounts. Even though its leadership in world trade was slowly being transferred to the United States, Britain's international accounts were not weak at the outbreak of World War I. It was the war, together with Britain's unavoidable sale of some foreign assets, that contributed to the deterioration in its balance of payments.

Between the World Wars.—Between World Wars I and II the volume of world trade in manufactures never appreciably exceeded that of 1913; the peak of 1926–30 was hardly above the 1913 level; the average of 1931–35 was only 76% of 1913; and the average of 1936–38 was 92%. The fact that Britain's share was declining rapidly within this reduced total was a significant factor in impeding adjustment of its international accounts. The external strains of the interwar period were in considerable part the result of the need for Europe—and Britain in particular—to adapt itself to this changing situation.

Furthermore, in the 1920s Britain's deficit between direct imports from, and exports to, the United States increased at the very time that invisible income (*i.e.*, shipping, insurance, banking receipts, etc.) from the United States decreased. The United States looked increasingly to the non-European world for imports, and Britain's share in U.S. trade continually declined. This decline was partially the result of a widening gap in productivity between the United States and Britain.

The gold standard, which Britain restored in 1925 following the period of currency disorder and inflation which engulfed Europe, broke down in 1931. The great depression aggravated the external strains; comparatively free multilateral trade proved to be incompatible with mass unemployment. Multinational clearing disintegrated as restrictions on trade became ever more severe. The gains from the devaluation of sterling in 1931 proved short-lived; this action started a chain reaction that included devaluation of the U.S. dollar in 1933–34 and did not end until there had been further devaluations of the French and Belgian francs. Meanwhile, Britain (and many other countries) in the later 1930s had turned toward bilateral trade and direct controls as an effective method of relieving external strains. Despite all its efforts, Britain by 1938 was compelled to liquidate a small portion of its overseas assets to bring its international accounts into balance.

Effect of World War II.—World War II dealt a staggering blow to Britain's balance of payments. Loss of income from overseas investments and from services impaired the nation's ability to meet the long-standing trade deficit with the United States and Canada. The east-west barrier, the position of Germany and chaotic conditions in the far east and middle east increased British dependence on the dollar area. In effect, the prewar pattern of trade between Britain and the rest of Europe, and between Britain and the non-European world, had been practically destroyed.

Britain's postwar recovery in its balance of payments was irregular. Underlying the transitional problems was the long-term conjuncture of the great structural change in Britain's international position and the growing predominance in the world of a relatively self-contained, industrially efficient but highly unstable United States. Over the whole process of British reconstruction loomed the interrelated maladies of domestic inflation and external deficits which led to such events as the British convertibility crisis of 1947. Following that crisis, Britain made remarkable headway with the external problem, largely through a budgetary attack on inflation and, later, the European Recovery program (*q.v.*). Nevertheless, Britain suffered another reserve crisis in 1949 caused partially by a direct increase in Britain's own dollar gap (to some extent a result of "suppressed inflation"), a loss of dollar earnings by other members of the sterling area (occasioned by a recession in the United States) and an acceleration of a slow drain of gold to Belgium and Switzerland. The ominous decline in reserves compelled Britain to devalue the pound in Sept. 1949. Mass devaluations followed. Devaluation of the pound sterling, coupled with increased productivity at home and elsewhere, rapidly improved Britain's reserves. The deficit on current account with the United States and Canada was much reduced, and the surplus with the entire world was increased greatly. The over-all improvement

was partly attributable to the expansion in net invisible earnings and to the continued restriction of the volume of imports. Certainly the latter could not have been accomplished without the most severe austerity in Britain.

Following the devaluations, the balance-of-payments position of the entire sterling area improved even more strikingly than did that of Britain. Actually, the sterling area raw material exporting countries had sold large quantities of wool, tin, rubber and cocoa at high prices, particularly to the United States and continental Europe, and had to a large extent "banked" the proceeds with the United Kingdom. The increase in reserves was therefore quite accidental; for the most part it was the result of the outbreak of war in Korea in 1950. Although this proved to be, with subsequent price decline of important raw materials, a temporary financial improvement, more fundamental forces were operating toward the strengthening of Britain's external accounts.

The continuing growth of British productivity during the 1950s and the more effective anti-inflationary monetary and fiscal policies helped immeasurably to reduce Britain's dollar deficit; indeed, in some years dollar surpluses were recorded. These factors, coupled with the high rates of economic growth in western Europe, Japan and the commonwealth, as well as the improvement in the United Kingdom's terms of trade, enabled it to increase its gold and dollar reserves. In 1958, with the collaboration of other western European countries, Britain consolidated the strength of its economy, which had been steadily built up in the preceding years, by establishing nonresident convertibility. As from Dec. 1958 British pounds earned by residents outside the sterling area were designated freely convertible into gold, dollars or any other currency. In effect, by 1960 the United Kingdom had achieved a workable balance in its international accounts. Despite all the stresses of World Wars I and II and their aftermaths, the pound—the international currency of the sterling area—remained one of the two leading world currencies. An important problem which remained unanswered, however, concerned the ability of the United Kingdom to maintain an appreciable rate of economic growth without rapidly encountering balance-of-payments strains. The complexity of the problems was evidenced by a recurrence of a balance-of-payments crisis in 1961. *See* STERLING AREA.

U.S. BALANCE OF PAYMENTS

For many years the United States had a merchandise export surplus. From 1876 to 1960 there were only three years (none after 1894) when it had a merchandise import surplus. The reasons for this development were many and varied. They included a deliberate national policy of high tariff protection; the continental character and climate of the United States; the abundance, richness and variety of its natural resources; the great distances from most foreign trading and producing centres; the protection given inland producers by high internal transportation costs; the technical skills of its people; the technological efficiency of its mass-scale production and distribution in manufacturing; the generally well-organized and mechanized agriculture; the greater tendency to generate excess capacity than other developed countries; and the nature of its commodity imports. All these factors tended to limit the expansion of American imports without heavy cost either in the production of domestic substitutes or in the deprivation of important products. Thus, compared with other important trading countries, the United States spent through the years an extremely small proportion of any dollar increases in national income on foreign products.

In the period before World War I, the United States export surplus was a sign of healthy economic development. It supplied foreign exchange for payments on foreign debt. In the 1920s, when the United States became a creditor nation, it preserved its export surplus partly by making large loans to foreign countries. Other large debit items, purchases of shipping and insurance services, tourists' expenditures abroad and remittances by immigrants and charitable foundations contributed substantially to the foreign supply of dollars.

Depression and War.—The depression of the 1930s altered these conditions. Domestic investment, particularly during the spurt before the depression, tended to generate a rate of growth in income and an excess of planned saving over planned investment. With the coming of the depression, the disparity between the growth in physical capacity to produce and the growth of current demand became acute. As returns on domestic capital declined and political and economic troubles developed abroad, the excess of planned saving not only failed to be invested abroad but the flow of capital was reversed from a net outflow to a net inflow. The nation maintained a merchandise export surplus by readily importing the precious metals. From 1934 until the outbreak of World War II, rising levels of production and moderate reduction in tariffs contributed materially to a closer approach to balance in the nation's current account. On the whole, U.S. industrial production, exports and imports moved together. During the period of U.S. participation as an active belligerent in World War II, more than 80% of total U.S. merchandise transfers represented lend-lease. In addition, for the three and one-half years following the war (from July 1, 1945, through 1948), net utilized foreign grants and credits of the U.S. government covered more than one-third of the United States total exports of goods and services.

Long-Range Trends.—What is often overlooked, however, is that powerful forces have for long been working toward international equilibration of U.S. external accounts. Thus, abstracting from the abnormal conditions of World War I and reconstruction, there has been a strong tendency since 1909 for the United States to have an excess of imports over exports of crude foodstuffs. From 1923 to 1960 U.S. imports exceeded exports of crude foodstuffs virtually every year, despite depression conditions of the early 1930s. Similarly, since 1915, the U.S. excess of imports over exports of crude materials has been quite general, the only important exceptions being those of the years 1932–33. More noteworthy has been the long-term trend toward balance of U.S. trade in manufactured foodstuffs and in semifinished manufactures. From 1876 until 1932, U.S. exports of manufactured foodstuffs exceeded imports in every year but 1920. However, from 1932 to 1940 the trend was reversed; and this new tendency toward net importation of manufactured foodstuffs was gradually resumed after World War II, although from 1953 to 1956 the structural maladjustments in U.S. agriculture brought about an excess of exports over imports of those products. From 1957 to 1960 imports of manufactured foodstuffs once again exceeded exports. Further, in most years from 1897 to 1921, U.S. exports of semifinished manufactures exceeded imports, but from 1922 until 1936 imports exceeded exports in every year. This trend was also resumed after World War II, although in the recession year of 1957 exports of semifinished manufactures exceeded imports. Lastly, U.S. exports of finished manufactures, the trade balance of which had been active since 1898, did not show a tendency to rise in the postwar period, whereas U.S. imports of finished manufactures continued steadily to expand.

Indeed, with one insignificant exception, throughout the 1950s U.S. total expenditures on imports of goods and services, donations and investment abroad exceeded foreign expenditures in the United States. The excess of total exports over imports in goods and services had in effect become insufficient to cover U.S. capital exports, governmental aid and expenditures. Measured in terms of gold outflow and the increase of foreign short-term balances held in the United States, from 1950 to 1957 the average annual deficit for the United States was about $1,000,000,000. In 1957 there was no such deficit, but it reached the embarrassingly large figure of over $3,000,000,000 in 1958 and 1959. The deficit in 1958 comprised a gold outflow of $2,300,000,000 and an increase of foreign short-term balances of $1,100,000,000; in 1959 it comprised a gold outflow of $770,000,000 and an increase of foreign short-term balances of $2,300,000,000. In the latter year, for the first time in the 20th century, the United States had an excess of commercial imports over exports of goods and services. It also had a deficit on total current account (items 1 through 10) and in goods and services and private donations (items 1 through 9).

During the first decade after World War II, the remarkable economic expansion in the United States and elsewhere, together with

continued foreign assistance and tariff reductions, strengthened the long-term forces operating toward balance in U.S. international accounts. But at the close of the 1950s, events exhibited a "pendular" reaction. Supply conditions in western Europe had greatly improved. The high rates of economic growth at stable prices in the Federal Republic of Germany and at falling ones in Japan enabled them to expand their share of world exports of manufactures while that of the United States declined. The magnitude of the U.S. deficits was aggravated by a sharp rise in U.S. imports relative to that of western Europe, an unusually prolonged steel strike, exceptionally low cotton exports, conversion to the production of commercial jet airplanes and abnormally large imports of small cars. The evidence does not disclose that U.S. prices had been rising appreciably as compared with those of most other industrial countries. With the relative expansion in Europe during 1960 the U.S. balance of payments in goods and services strongly improved. Nevertheless, the continuation of substantial deficits in the early 1960s, measured in terms of the outflow of gold and net increases in foreign holdings of liquid dollar assets, gave concern on both sides of the Atlantic over the long-term equilibrium of the U.S. balance of payments.

Balance-of-Payments Equilibrium.—Balances of payments are seldom in equilibrium in the theoretical sense that a small displacement of exports, imports or capital items would tend to be corrected and the original balance restored. In practice, equilibrium in a nation's balance of payments implies the absence of severe drain, or accumulation, of foreign reserves. Such drains may be the direct result of an excessive amount of domestic money being exchanged into foreign money. This may indicate that either the debtor or the creditor nation's monetary, fiscal and wage policies—and the resulting money incomes and product prices—are incompatible with the foreign-exchange rates. After World War II many countries found themselves in this situation vis-à-vis the United States and, by Sept. 1949, felt compelled to devalue their currencies. A persistent drain of reserves arising from an import balance in one of the selections of accounts (*e.g.*, total goods and services) may indicate that the nation in the past has been able to live partly on its foreign reserves and assets or to secure foreign loans or grants. Mounting international indebtedness may also be the result of unfulfilled or inconsistent plans with respect to domestic production and expenditures on the one hand, and imports and exports on the other. In such instances the gap between imports and exports has often been filled by foreign borrowing. Differential rates of interest may also contribute to international disequilibrium; thus the lower net-interest rates of the United States as compared with those of many other industrial countries have recently compounded the difficulty for U.S. net exports to cover capital outflows, governmental aid and expenditures.

Regardless of the source of disequilibrium, the problem of adjustment in a nation's balance of payments affects the creditor as well as the debtor. In the long term, measures appropriate to the debtor will help solve the problems of the creditor, and measures appropriate to the creditor will help solve the problems of the debtor. But in the short term all policies are not equally acceptable, and creditors as well as debtors are tempted to resort to extreme national measures without regard for their effects on the world economy as a whole.

FOREIGN-EXCHANGE CONTROLS

As a consequence of the great depression, and attendant capital flight, from the 1930s a major complication arose in the international mechanism of adjustment, viz., the development of foreign-exchange controls. These controls restrict operations in all or specific foreign currencies on both current and capital account. They are usually administered by the central bank as the treasury's agent, and are invariably associated with trade controls. They take many forms, ranging from the licensing of all transactions involving foreign exchange to the supervision of transactions involving only specific foreign currencies or those of residents of specified countries. Nonetheless, they always constitute a method of rationing foreign currencies, particularly those which are scarce, and of ensuring that receipts of such foreign exchange are diverted into authorized channels.

The chief function of exchange controls is to prevent or redress an adverse balance of payments by limiting purchases of foreign exchange to an amount not in excess of foreign-exchange receipts. Usually, this entails setting a rate, or rates, at which exchange shall be bought and sold. When a single rate is established, it is normally higher than the rate that would prevail in a free market. Consequently, it tends to curb exports and stimulate imports. When multiple rates are established, they have the effect of differentiating between prices charged at home and abroad for specified exports and imports. The value of the currency is kept uniform for all residents with respect to their purchases of domestic products; but the multiple rates fix different prices for the same goods at home and abroad by stipulating different exchange rates for the various uses to which foreign exchange may be put. Although this practice may strengthen a country's balance of payments, it is a form of monopolistic price discrimination in international trade.

Most noncommunist countries have had occasion to adopt foreign-exchange controls out of necessity rather than preference. In periods of emergency it has often been impossible to achieve balance-of-payments equilibrium through the operation of demand and supply on the foreign-exchange market. Once adopted by some important country or countries, exchange controls have provided a source of special advantage as an instrument of trade bargaining; hence their tendency to spread. They have also been used primarily for domestic reasons, such as to insulate an economy from external inflationary or deflationary pressures, or to assist in national economic planning and development. However, in economies that are not centrally planned, exchange controls have had a tendency to direct trade into uneconomic channels, deteriorate its quality and reduce the extent of its potential contribution to the well-being of the participating countries. These factors are particularly relevant to full-employment conditions, for then exchange controls and their associated practices act as a constraint against further economic expansion. When the emergency that brought about their adoption has been removed, most noncommunist countries have tended to do away with exchange controls on trade account. They have usually been maintained on capital account, however, in order to control the flow of domestic versus foreign investment, and to deal with emergency conditions of capital flight.

Freely Fluctuating Rates.—Under normal circumstances international payments equilibrium might be achieved in a free system in which everyone is permitted to buy and sell foreign exchange in unlimited amounts. Shifts in demand and supply in foreign currencies would bring about changes in exchange rates which, in turn, would equalize the demand and supply for foreign currencies. If a country's demand for foreign exchange were to exceed supply, the value of foreign currencies would tend to rise relative to the value of the domestic currency. Its imports would tend to fall and its exports rise, leading toward the restoration of equilibrium. This process of international equilibration, it will be observed, requires no disinflationary pressures in the country suffering from a balance-of-payments deficit; on the contrary, it tends to raise prices domestically in terms of the national currency but to lower them in terms of foreign currencies.

Despite its simplicity the system of freely fluctuating exchange rates has rarely been recommended. Almost no country for which foreign trade has been of great importance has ever been willing for long to tolerate completely uncushioned, fluctuating exchange rates. The reasons for this have been many and complex; they are grounded in the fact that fluctuating exchange rates are a powerful vehicle for disruptive speculation. A small, well-informed group customarily deals in the exchanges. In these markets there are no storage expenses, no physical deterioration or obsolescence caused by changes in tastes or wants. The asset in question is for practical purposes homogeneous, standardized and without grades. Brokerage charges are minimal, the level of commissions by middlemen being lower than in any other field of speculation except national bond markets. The hedge normally earns

income for the speculator and, be it foreign exchange or gold, it may be the best hedge with respect to expectations of a decline in the general price level. Lastly, there are no physical restraints, such as cost of production, on the possible extent of the swing downward in the value of a single country's currency. Exchange-rate fluctuations are often self-propelling and lead away from, rather than toward, international payments equilibrium.

It is generally recognized that once the brake of reasonably stable exchange rates is removed, the last significant obstacle to irresponsible monetary and fiscal behaviour, for a long period and for many countries, may also be removed. In addition, experience has proved that fluctuating exchange rates result in risks for foreign trade and investment which are economically costly, and for which the development of forward-exchange markets and other facilities for hedging provide only a very limited palliative. Nor is it desirable to let exchange rates fluctuate freely in response to temporary changes in demand and supply. Such fluctuations cause adjustments in production and transfers of resources which also are costly and should be avoided if the disturbance is merely of a short-term character. The crux of the matter is that changes in exchange rates are different from other price changes: they affect, directly, all prices of internationally traded commodities and, indirectly, many prices in the national economy. As a prerequisite for international economic stability, key trading countries must therefore maintain reasonably stable exchange rates.

Stable Rates.—Rigidly stable exchange rates also have their drawbacks, for under certain circumstances they tend to generate deflation. Between 1870 and 1914, when the gold standard was an almost universally accepted institution in the western world, gold-standard countries tied their currencies to each other in terms of gold. Residents of one gold-standard country were permitted to procure money from another gold-standard country at a rate of exchange determined by the gold-weight ratio of the two currency units and by the cost involved in sending the gold from one country to the other. Thus the price of the pound sterling in terms of dollars could not rise beyond the so-called upper or U.S. gold-export point, since at this point it would become cheaper to purchase pounds by exchanging dollars into gold in the United States and to ship the gold to Great Britain. Similarly, the price of the pound sterling could not drop below the lower or U.S. gold-import point, since at this point it would become cheaper to purchase dollars by exchanging pounds into gold in Great Britain and shipping the gold to the United States. Within limits of the gold points, the gold standard therefore directly achieved stable exchange rates. Indirectly, it contributed to the automatic operation of the international mechanism by stimulating the inflow of short-term funds to the country whose exchange rate had fallen to the lower limit and was expected soon to rise.

Should a country's demand for foreign exchange tend greatly to exceed the supply, however, the movement of short-term funds would be insufficient to re-establish equilibrium. Nevertheless, the gold-standard mechanism would still tend to produce an adjustment automatically by an outflow of gold from the country that had developed a deficit, and an inflow of gold into the country that had developed a surplus. As gold constituted the basis of the monetary system under the gold standard, a reduction in the gold base could lead to a contraction of money and credit of a country in amount several times larger than the gold export, and conversely. The outflow of gold would tend to depress prices, and if the wage-price level were not perfectly flexible, this would also tend to depress real incomes. These changes in turn would tend to reduce imports and expand exports of the country losing gold, while the opposite changes would tend to raise imports and lower exports of the country gaining gold. The monetary contraction of the country losing gold relative to the countries gaining it would have the additional effect of raising interest rates in the former and lowering them in the latter. Normally, this would aid the process of equilibration by attracting foreign capital to the country which had developed the deficit. Equilibrium would therefore tend to be restored with a minimum gold outflow, an export surplus and an inflow of foreign capital.

The gold standard clearly was conducive to the interdependent growth of free multilateral trade and large-scale private capital movements. It helped integrate the monetary and credit policies of the gold-standard countries. It also was compatible with the objectives of reasonable price level stability and satisfactory growth rates. But it could not prevent world-wide inflations or deflations. If gold-standard countries were simultaneously to go through an inflation, the gold-flow mechanism would only keep them in line by way of a gold flow from the more to the less inflationary countries. A parallel rise in prices would not set the mechanism in motion; and similarly for the case of simultaneous deflation. Furthermore, even in the 19th century, prices and costs were not flexible enough for a smooth adjustment in the event of a gold outflow. Wages were inflexible downward. Attempts to reduce prices through credit contraction often lowered profits and increased unemployment. In fact, the gold standard failed to accomplish one of the most significant aims of virtually all modern nations, the avoidance of major depressions and mass unemployment. When the gold standard was restored in the latter 1920s, its weaknesses became even more apparent. Not only had the United States replaced Britain as the pivotal country in world trade, and thus transformed the process of international equilibration, but economic rigidities had also increased: the rules, as well as objectives, of the gold standard became increasingly incompatible with the new conditions.

As an international mechanism, the gold standard failed and crumbled with the great depression. Experience and theory had shown that deflationary policies might not improve a country's balance of payments during a world crisis. Moreover, countries suffering from external deficits could not tolerate an international mechanism which intensified unemployment. Hence, after the depressed conditions of the early 1930s, most governments eschewed financial contraction and undertook measures to increase the volume of output and employment.

A good deal of the theoretical literature of the period swept aside the classical assumptions of maintaining stable exchange rates and of relying on internal price adjustments to bear the brunt of the balancing process. Stress was laid, instead, on the equilibrating effects through income changes and on the insensitivity of internal adjustments to external forces. Emphasis was placed on greater exchange-rate variation and on trade controls as a guide to external policy; on internal stability at full employment and on effective demand as a guide to internal policy. Primarily, the equilibration of international accounts was achieved, in fact, through the adjustment of imports and exports to changes in the levels of production and income at home and abroad. When employment and production increased in one country, its imports would rise. The export industries in the countries supplying these goods would expand. Their income and employment would rise in turn, and their imports would increase. This adjustment process could readily cause a deficit in the country initiating the change, for the rise in its imports would not be followed by an immediate rise in its exports. A new balance would nevertheless tend to be established as an expansion of production, income and prices in the countries that had been stimulated would bring about an increase in their imports. On similar reasoning, a recession or depression in an important trading country could cause a contagious economic contraction, for the decline in its production would tend to result in a fall in its imports, and hence a fall in production and income abroad.

MONETARY AGREEMENT

It can readily be understood that when the representatives to the United Nations Monetary and Financial conference met in 1944 at Bretton Woods, N.H., to establish the International Monetary fund (IMF), they did not recommend a document that would have tied the hands of governments to rigidly stable exchange rates. Nor did they recommend freely fluctuating exchange rates or the complete abolition of foreign-exchange controls.

International Monetary Fund.—The main purposes of the IMF were to promote international monetary co-operation; to facilitate the expansion and balanced growth of multilateral trade; to promote exchange stability and avoid competitive exchange

depreciation; to assist in the establishment of free international payments and convertibility on current account without discriminatory trade or exchange restrictions; and to make international currency resources available to the contracting members. To this end, the agreement which came into force in 1945 assigned to each member a quota in the fund on which it could draw to cover a deficit in its balance of payments. The subscription of each member was equal to its quota, 25% of which was paid in gold (or, lacking this amount, 10% of its net official holdings of gold and U.S. dollars) and the balance in its own currency. Although the countries agreed to promote general stability of exchange rates, the par value of a member's currency could be changed by 10%, and the fund merely notified of such action. Changes in excess of 10% would require the concurrence of the fund.

The contracting members thus anticipated that exchange-rate changes would be more flexible in the postwar era than they had been under the gold standard, but that competitive exchange depreciation would be avoided. The new arrangements would give the member countries greater freedom with respect to domestic financial policies than did the gold standard. A country would be able to combat certain kinds of depressions or recessions by expanding effective demand, even though such policies might lead to an adverse balance of payments and a reduction of its exchange rate. On the other hand, if a country should suffer from a balance-of-payments deficit engendered by expansionary financial policies, the fund could withhold aid until the member adopted noninflationary policies.

After the establishment of the fund, the international mechanism of western nations consisted of arrangements lying between that of the gold standard and completely flexible exchange rates, with some measure of direct foreign-exchange controls. These arrangements have been used with a view to achieve external balance without sacrificing prevalent domestic economic objectives: a high average level of employment; avoidance of significant cyclical instability; appreciable long-run rates of growth; improvement in the average level of well-being; equity in the distribution of income; and a reasonably stable general price level. Within the limits of these objectives, most western nations have also endeavoured to keep their exchange rates stable over extended periods of time. There has thus been a general weakening in the emphasis on exchange-rate stability, although key countries have shown resolve to alter their own exchange rates only as a measure of last resort. All western governments have demonstrated greater determination to counteract economic fluctuations by central bank and fiscal policies. They have considered it undesirable to permit the self-regulating forces of the international mechanism to operate whenever such forces threatened the objectives of economic growth or price-level stability. In time of balance-of-payments deficit, some nations have therefore refused to follow contractionary policies; in time of surplus and full employment, others have been reluctant to follow expansionary policies. Consequently, the operation of the international mechanism of adjustment has been seriously curtailed.

In the early postwar years the IMF was unable to deal effectively with the problem of international disequilibrium. Dollar deficits were inextricably interwoven with the gigantic task of European reconstruction; and the fund was never intended, nor did it possess the resources, to cope with these problems. Among other things, western European countries required larger international reserves. From 1946 to 1949 various types of monetary clearing agreements predominated in Europe. They usually involved an arrangement between the central banks of two countries; the importers of each country paid the sums they owed to the exporters of the other into an account of their own central bank. At specified intervals, the two central banks offset their mutual claims. If the imports of the two countries did not balance—as they usually did not—one country would for a considerable time accumulate claims on the other.

European Payments Union.—In 1950 these emergency arrangements were replaced in Europe by a new monetary agreement called the European Payments union (E.P.U.). The E.P.U. was a multilateral clearing agreement which allowed each country to offset a deficit in its balance of payments with any one of the member countries against surpluses with others. The clearing took place at the end of each month. If the country emerged with an over-all deficit vis-à-vis the rest of the group, the E.P.U. automatically extended credit to it either for the whole amount of the deficit or for part of it, depending on its cumulative debtor position. The difference between the deficit and the amount of credit obtained had to be paid in gold. Once the country had exhausted the quota allotted to it, the whole of the deficit had to be paid in gold. Similarly, a country that emerged with a surplus had to give credit to the E.P.U. to the extent of the whole or part of the surplus depending on its cumulative creditor position. Once it had reached the limit of its quota, the country received an agreed-upon proportion of the surplus in gold from the E.P.U. and granted the remaining credit to the E.P.U. The E.P.U. was renewed from year to year, until it was terminated in 1958.

European Monetary Agreement.—By that time western European countries felt able to make a major monetary reform to eliminate the discrimination between dollar and nondollar currencies in their formal exchange arrangements. With their adoption of nonresident convertibility in 1958, the E.P.U. was dissolved and its termination brought into force the European Monetary agreement (E.M.A.). This agreement was signed as early as 1955 by the members of E.P.U. Under E.M.A., the automatic credit arrangement was abolished but member countries were obliged to make available limited amounts of very short-term finance. Credits might be granted to assist in meeting temporary balance-of-payments difficulties, the approval of each application being subject to examination of the merits of the case.

The IMF had increased its quotas in 1958 and expanded its stand-by reserve arrangements. These acts were of importance in reinforcing the confidence of western Europe to establish nonresident convertibility. Even of greater significance were the deficits of the United States in improving the international liquidity position of its trading partners. These latter deficits were of great magnitude and clearly could not be continued. Hence, in 1961, the Organization for European Economic Co-operation (O.E.E.C.) was transformed into the Organization for Economic Co-operation and Development (O.E.C.D.) with the full participation of the United States and Canada. It was established for the express purpose of achieving closer economic collaboration of the noncommunist world; and particularly to obtain larger contributions from western European countries and Japan to the development of newly independent countries. Western institutions were substantially strengthened to deal with moderate and isolated balance-of-payments strains, but they would be inadequate to meet a more severe and general international financial crisis.

In order to contribute to the defense and development of the noncommunist world, the United States is obliged to maintain an excess of exports over imports of goods and services. To achieve these ends, the United States and western Europe were faced in the early 1960s with the need to make serious adjustments. As for the United States, a substantial export surplus at appreciable rates of economic growth required the maintenance of a competitive price level. As for western Europe, it was essential to recognize that the burden of adjustment was as much the responsibility of countries with balance-of-payments surpluses as it was of countries with balance-of-payments deficits.

INTERNATIONAL REFUGEE ORGANIZATION, commonly known as the IRO, was a temporary specialized agency of the United Nations, formally established in 1946, which assisted refugees and displaced persons remaining in many countries of Europe and China after World War II who either could not return to their countries of origin or were unwilling to return for political reasons. Between July 1947 and Jan. 1952 IRO cared for over 1,500,000 persons in special camps, particularly in Germany and Austria, pending repatriation or resettlement in other countries.

Functions.—The services supplied by IRO were care and maintenance in the camps, including food and clothing, medical care, vocational training and orientation in preparation for resettlement and transportation to overseas countries of permanent resettlement. IRO also conducted an extensive tracing service in many countries to find lost relatives and to reunite families, and assisted many thousands of unaccompanied children to rejoin their parents or to find new foster homes. The aged and the ill who could not qualify for admission to countries of immigration were placed in institutions for permanent care.

Beginning operations on July 1, 1947, the IRO preparatory commission took over from its principal predecessor organization, the United Nations Relief and Rehabilitation administration (UNRRA) (*q.v.*), the administration of the refugee camps in Germany and Austria and assisted many thousands of refugees resident temporarily in other European countries and in countries of North Africa. UNRRA had previously been engaged in collaboration with the occupying military authorities in Germany and Austria in assisting the repatriation of some 7,500,000 displaced persons to their home countries immediately after the war. IRO assisted the remaining 1,500,000 refugees and displaced persons who exercised their freedom of choice, recognized by the UN, not to return to their countries of origin for political or other reasons. IRO also assumed at that time the responsibilities for the legal protection of refugees and for their resettlement in other countries previously carried out by the Intergovernmental Committee on Refugees, which had been organized in London in 1939 and which terminated its activities upon the organization of IRO.

Participation.—During the five years of IRO operations, member governments contributed $400,000,000 to IRO expenditures which included over $195,000,000 for the transportation overseas of approximately 1,000,000 refugees who were accepted by Australia, Canada, the United States and the Latin-American countries. About 23,000 refugees of European origin in China were assisted to find permanent homes in other countries. When IRO terminated its activities in Jan. 1952, about 500,000 refugees remained in an unsettled state in Europe of whom 200,000 were still living in camps. Eighteen governments participated as members of IRO and contributed to its expenditures: Australia, Belgium, Brazil, Canada, China, Denmark, Dominican Republic, France, Guatemala, Iceland, Italy, Luxembourg, the Netherlands, New Zealand, Norway, the United Kingdom, the United States and Venezuela. *See* also Refugees; United Nations.

INTERNATIONAL RELATIONS (ARTICLES ON). Attempts to systematize the study of international relations date from antiquity. In the 20th century, however, the subject has acquired a new urgency. Because of the increasing destructiveness of war, the rise of new ideologies, the decline of colonialism, the establishment of universal international organizations and the increasing interdependence of all peoples through modern means of communication and transport, governments and peoples have been forced to pay primary attention to international relations. It has become an accepted field of education and research, and efforts have been made to state its principles in a unified discipline. International Relations gives an introductory survey of this discipline, which has attempted to analyze the conditions, needs and aspirations influencing the foreign policies of nations; the patterns of power, interest and justification that have developed both universally and in regions; and the processes of accommodation, adjustment and change seeking to close the gap between practice and theory.

The evolution of international law, its scope, and the theoretical and practical basis of its authority are treated in International Law, Public. The body of rules governing issues that arise between individuals belonging to different nations or between an individual and a nation other than his own, sometimes known as private international law, is discussed in Conflict of Laws.

Diplomacy deals with the conduct of international relations as a profession; the evolution of its traditions and methods; and the impact on these of World Wars I and II. Ambassador describes the nature of the highest diplomatic rank.

Major controversies of the 20th century have centred around the conditions under which a new regime is to be accepted as the legal representative of a state, or a newly established state is to be accepted in the family of nations. The factors involved in this question are discussed in Recognition, Diplomatic.

The varying degrees of authority exercised by fully and partially sovereign states are discussed in Sovereignty. Articles dealing with the influence of states beyond their national borders include Empire; Hegemony; Imperialism; Mandate; Protectorate; Spheres of Influence; Suzerainty.

Attempts to map a road to peace, and the methods that have been tried and proposed, are discussed in Peace, International. Among the articles dealing with individual phases of the quest for peace are Arbitration, International; Disarmament; International Organizations; Pacifism; and World Government Movements.

The rise and fall of the first global organization for collective security are chronicled in League of Nations. The organization that inherited the League's problems is discussed in United Nations, an article that describes the major executive and administrative units of the UN; its specialized agencies; and its successes and frustrations when its machinery has been called into action. Certain ideals which the UN was intended to realize are discussed in Atlantic Charter; Human Rights; and Self-Determination.

International Court of Justice describes the history, organization and administrative procedures of the chief judicial agency of the UN. Among other articles dealing with UN agencies and activities are Food and Agriculture Organization; International Labour Organization; Trusteeship System; United Nations Educational, Scientific and Cultural Organization; Postal Services; and World Health Organization.

Among many articles dealing with international economics are Bank for Reconstruction and Development, International; Capital, Export of; Cartel; Commercial Treaties; Economic Union; International Payments; International Trade Associations and Congresses; Mercantile System; Shipping, History of; Tariff; Trade, International; Trade Routes; and Waterways, International.

International alignments in general are treated in Alliance; those sponsored by the U.S. include North Atlantic Treaty Organization and Southeast Asia Treaty Organization. Alignments associated with the U.S.S.R. are discussed in Communism; International, The; Mutual Economic Assistance, Council for; and Warsaw Treaty Organization. Economic aid programs of both the U.S. and the U.S.S.R. are discussed in Foreign Aid Programs.

The European common market is discussed in Economic Union.

Articles on other regional groupings in international relations include Monroe Doctrine; American States, Organization of; and Pan-European Movement. Articles on ethnological and religious groupings include Pan-Germanism; Pan-Islamism; Pan-Slavism; Pan-Turanianism; and Zionism.

Since international conferences and treaties made at them are

usually referred to by the name of the city where they were held, articles dealing with them will be found under such headings as BAGHDAD PACT; BANDUNG CONFERENCE; GENEVA SUMMIT CONFERENCE (1955); LOCARNO, PACT OF; SAN FRANCISCO CONFERENCE (1945); YALTA CONFERENCE (1945); and, for earlier conferences, under HAGUE CONFERENCES; WASHINGTON CONFERENCE; etc. Two key articles dealing with groups of conferences are PAN-AMERICAN CONFERENCES; and WORLD WAR II CONFERENCES, ALLIED, which treats all major Allied conferences (for example, those of Casablanca and Potsdam) with the exception of Yalta, which is the subject of the separate article listed above. The procedures usually followed in gatherings for the discussion of international issues are described in CONFERENCE. TREATY deals with methods of negotiation, the various types of treaty and the place of treaties in history and in the context of international law.

FAR EAST: RELATIONS WITH THE WEST surveys the history of these relations, from the Portuguese explorations of the 16th century to the political and military chain reactions that followed the rise of Communist China. EASTERN QUESTION similarly deals with the near east and middle east.

WAR examines military policy as a branch of foreign policy; also, it reviews ancient, medieval and modern types of war, their causes and their impact on civilization. Among other articles concerned with the repercussions of war on the international community are AGGRESSION; BLOCKADE; CONTRABAND; ECONOMIC WARFARE; ESPIONAGE; LAWS OF WAR; NEUTRALITY; PRIZE COURTS AND PRIZE LAW; PSYCHOLOGICAL WARFARE; and REFUGEES. Articles on many aspects of warfare are listed under MILITARY AFFAIRS (ARTICLES ON); NAVAL AFFAIRS (ARTICLES ON); AIR WARFARE.

The foreign policies of specific states are discussed in the general articles on those states.

A sound understanding of international relations calls for knowledge of many allied fields, the most obvious of which is covered in the survey article GEOGRAPHY. The use and misuse of geographical science in international relations are treated in GEOPOLITICS.

Among other important background articles are ANTHROPOLOGY (particularly the section *Applied Anthropology*); ATOMIC ENERGY; FOOD SUPPLY OF THE WORLD; MIGRATION; NATIONALISM; NATURAL RESOURCES; POPULATION; PROPAGANDA; PUBLIC OPINION; PSYCHOLOGY; RACES OF MANKIND; and SOCIAL ANTHROPOLOGY.

Biographical articles summarize the work of leaders in the field, from the classical commentator GROTIUS, HUGO to such modern authorities as ANZILOTTI, DIONISIO and WILSON, GEORGE GRAFTON.

INTERNATIONAL RELATIONS. In its broadest, literal meaning, this term denotes relations among the autonomous political units which today we call nations, or among individual members of such units. On the collective level, such relations can be political, military, economic or cultural; they can comprise all kinds of individual relations involving members of different nations. Yet when we refer to international relations as a distinct object of human action and understanding, we have in mind only those collective or individual relations, transcending national boundaries, which affect the position of nations vis-à-vis each other. International relations in this sense are political relations; they comprise, aside from the foreign policy of nations, all collective and individual relations which impinge upon the political position of a nation vis-à-vis other nations. The term in this sense is a synonym for foreign relations, as used, for instance, in the name "senate foreign relations committee."

International relations are as old as political history itself and have shown throughout the ages constant patterns of relationships and policies, whether entered into by hereditary monarchs or elective governments, cities or nation-states, continental empires or tiny principalities, ecclesiastic or secular rulers. The consistency of patterns beneath the variety of historic manifestations makes both historic understanding and theoretical analysis of international relations possible. Thus we are able to understand the international relations of the Greek city-states that Thucydides describes, the international relations of the Indian states of the 4th century B.C. from which Kautilya derived his philosophy, the international relations of the ancient near east of which the Old Testament tells, as well as those of the more recent past. By detecting in the international relations of different cultures and historic periods identical responses to identical challenges, we are able to develop certain theoretical propositions about international relations that are true regardless of time and place.

Basic Patterns.—The dynamic force that molds international relations is to be found in the aspirations for power of autonomous political units. These aspirations crystallize into three basic patterns: to keep one's power, to increase one's power, to demonstrate one's power. From these patterns three basic types of policy ensue: the policy of the *status quo*, the policy of imperialism and the policy of prestige. The clash of these policies —A trying to maintain the *status quo*, B trying to change it at the expense of A—leads to an unending struggle for power which characterizes all international relations. This struggle for power can be fought by two different means: diplomacy and military force. It leads of necessity to the balance of power through which nation A, either alone or in conjunction with other nations similarly threatened, tries to maintain itself against B. When A and B pursue their goals in conjunction with other nations, they embark upon a policy of alliances. When nations carry on the struggle for power by military means, they engage in an armaments race or war. When they try to justify and rationalize their position in the power struggle by reference to universal values, typically of a moral nature, they develop political ideologies. Continuous peaceful contacts among them lead to the development of an institutionalized diplomacy (*q.v.*).

Throughout the better part of history, several systems of international relations have existed side by side with little or no contact among them. Until the discovery of America, the American system or systems of international relations led a completely separate existence. The Chinese and Indian systems had only intermittent contacts with others.

Three different patterns of international relations can be distinguished according to the distribution of power within them: multiple, bipolar and imperial systems. The multiple system is distinguished by a number of units of approximately equal strength which combine and oppose each other in ever-changing alignments. Its main characteristics are flexibility, uncertainty as to the relative strength and future policies of its members and the propensity for limited, inconclusive wars. The European state system, from the end of the Thirty Years' War in 1648 to the beginning of World War I in 1914, with the exception of the period of the Napoleonic Wars, conformed to this pattern.

The bipolar system is characterized by the predominance of two major powers of approximately equal strength, around which the other members are grouped in different degrees of closeness. This system is rigid and stable as long as the approximately equal distribution of power between its two predominant members persists. Any marked shift in that distribution threatens the system with destruction. The structure of international relations that emerged from World War II exemplifies this pattern.

The imperial system consists of one predominant nation with a number of subordinate members clustered around it. The stability of such a system is great, and conflicts within it tend to be marginal. Its existence can be threatened by the disintegration of the predominant member, the rise of a number of subordinate members to a position from which they can challenge the predominant one, or by a challenge from outside the system. The system of international relations dominated by the Roman empire is the classic example of this pattern.

Changes in Modern Times.—International relations have undergone in modern times four drastic changes: the formerly separate systems of international relations have merged into one world-wide system; the predominance of the European system has disappeared; the possibility and actuality of total war have come to dominate the international scene; the feasibility of universal destruction with nuclear weapons has radically altered the

function of force as a means to the ends of foreign policy. While the first three changes do not affect the dynamics and structure of international relations as we have known them since the beginning of history, the last constitutes a veritable revolution, the only one in recorded history, in the structure of international relations.

The expansion of the European state system into the other continents by means of colonial empires, starting early in the 16th century, broke down the barriers which had separated the different systems of international relations. They were all brought into contact with, and into some form of dependence upon, the European state system, and through it they came into contact with each other. The two world wars of the 20th century, in which most nations of the world participated, point in their very name to the transformation of a number of separate systems of international relations into one world-wide system. That process of political unification was greatly advanced and expanded to the individual sphere through the development of the technology of transportation and communications. This development started with the great voyages at the end of the 15th century and culminated in the drastic reduction of geographic distances for transportation and the virtual obliteration of the limits of time and space for communications.

The last phase of this transformation of international relations into a world-wide system, covering roughly the period from the end of World War I to the aftermath of World War II, coincides with a radical change in the distribution of power within the system. From the beginning of the 16th century to World War I the European system provided the dynamics and the preponderant power for this transformation; now two nations, either completely or predominantly non-European—the United States and the Soviet Union—have taken its place. This decline of Europe as the political centre of the world may be said to have started with the Monroe Doctrine of 1823 declaring the mutual political independence of Europe and the western hemisphere. This declaration foreshadowed the fragmentation of the European empires which was virtually consummated after World War II in the colonial revolutions sweeping Africa and Asia. Most of the colonial possessions of European nations, one after the other, gained their national independence, and many of them either withdrew their political support from the European nations or joined their enemies. The outstanding examples of these two different forms of political emancipation are India and China.

The decline of Europe resulting from the colonial revolutions coincided with the rise to predominance of formerly backward nations such as Russia and China. The technological unification of the world gave these nations the tools to transform their superior potential in geography, population and natural resources into the actuality of national power.

Total War.—The decisive factors in the decline of Europe as the political centre of the world were the two world wars of the 20th century. At the same time that they weakened the main European nations in their human and material resources, these conflicts brought non-European nations to the fore—the United States and Japan in consequence of World War I, the United States and the Soviet Union in consequence of World War II. These two world wars differed not only in their consequences but also in their intrinsic character from other wars fought in the western world in modern times. Most of the latter were limited wars in that only a fraction of the total human and material resources of the belligerents was committed to them. Only a fraction of the total population was morally identified with these wars and suffered from them, and each war was waged only for limited objectives. The two world wars and those for which the most powerful nations continued to prepare were total in all these four respects. The actuality and threat of total war were, indeed, the most important distinctive characteristics of international relations in the mid-20th century. They were due to an unprecedented accumulation of destructive power in the hands of the most powerful nations and to the incentive to use that power for national purposes. The accumulation of power resulted from drastic changes in the distribution of political and technological power in the world; the incentive was presented by the closing of the colonial frontier and the ascendancy of a universalistic nationalism.

Throughout the modern period, with the exception of the wars of religion of the 16th and 17th centuries and of the Napoleonic Wars, wars were limited in every respect. Power was so widely dispersed among a great number of sovereign states that no single state or possible combination of states was strong enough to gain more than limited objectives against its adversaries. The drastic reduction in the number of sovereign states and the resulting concentration of power in the hands of a few nations of the first rank, which occurred between the end of the Thirty Years' War and the end of World War II, created one precondition for total war. The treaty of Westphalia of 1648, for instance, reduced the number of sovereign states of which the German empire was composed from 900 to 355. The diet of Regensburg of 1803 eliminated 200 more. When the German confederation was founded in 1815, only 36 sovereign states were left to join it. The unification of Italy in 1861 and that of Germany in 1871 eliminated 31 additional sovereign states.

At the end of the Napoleonic Wars in 1815, only five nations of the first rank were left—Austria, France, Great Britain, Russia and Prussia. In the 1860s Italy and the United States joined them, followed toward the end of the century by Japan. At the beginning of World War I in 1914, eight nations were of the first rank, with Germany having replaced Prussia. After World War I the trend toward reduction of the number of sovereign states was reversed; their number about doubled because the Ottoman, Austro-Hungarian, British and French empires were broken up. Yet the trend toward concentration of more and more power in the hands of fewer and fewer states continued. At the end of World War II the number of nations of the first rank was reduced to two: the United States and the Soviet Union.

It is not by accident that the two most powerful nations, capable of threatening each other with total war, are also most advanced technologically and industrially. The mechanization of warfare in terms of weapons, supplies, transportation and communications requires, in case of actual hostilities, the virtually total commitment of the industrial productivity of the nation. This total commitment has been made possible by the enormous increase in economic productivity brought about by a series of technological and industrial revolutions, starting in the 18th century. By contrast, in earlier periods of history, economic productivity was so low that after it had barely provided for the needs of the population, little was left for military purposes. Thus premodern technology could support only limited war, while modern industry is productive enough to allow the commitment of the lion's share of its products for military purposes.

One incentive for the great nations to use this enormous productive power for the purposes of mutual destruction was provided by a change in international relations which can be called the disappearance of the colonial frontier. The generally limited character of the means and ends of foreign policy from the end of the middle ages to World War I was in good measure due to the opportunity for the great European nations to seek satisfaction for their aspirations for power not in all-out contests with each other but through competitive expansion into Africa, the Americas and the part of Asia bordering on the eastern oceans. Colonial competition and conflict during that period provided outlets through which the European nations could compete for power without endangering their existence. But by the beginning of the 20th century the colonial frontier was, for all practical purposes, closed. Virtually all politically weak or empty spaces around the globe had been transformed into colonies or spheres of influence by one or another of the European nations. From then on, as the two world wars showed, the great European powers, deprived of the colonial safety valve, fought each other not for limited advantage but for total stakes, and they could do so with the instruments of total war.

These stakes became total not only in that total war threatened the belligerents with total destruction, but also in that the issue over which nations competed and fought had become total. That issue was no longer a limited military or territorial advantage but the universal triumph or defeat of a particular philosophy and

way of life, which was supposed to be incarnate in a particular nation. While traditionally the international relations of the western world were carried on within the framework of common moral principles and of a common way of life, which imposed effective limitations upon the struggle for power, international relations in the mid-20th century were dominated by the conflict between democracy and Communism, each putting forth a universal message of salvation, each trying—with different intensity—to extend its dominion to all mankind, and each identified with one of the two great powers left in the world. Thus international relations came to be characterized not only by the traditional threat and use of military force on behalf of the aspirations of individual nations but also by a struggle for the minds of men. The proponents of the two antagonistic philosophies and ways of life, using the instruments of propaganda, foreign aid and foreign trade, endeavoured to gain the allegiance of uncommitted nations. By the same token, the traditional methods of diplomacy were in eclipse. Nations can negotiate and bargain about their interests and conclude compromises concerning them, but they feel that they cannot yield an inch where their philosophies and ways of life are at stake.

While similar situations have existed before, temporarily and on a limited scale, especially in periods of religious conflicts and wars, international relations after World Wars I and II were marked by a change in structure unprecedented in recorded history. Throughout history, there has existed a rational relationship between the threat and use of military force and the ends of foreign policy. It was rational for a nation to ask itself whether it could achieve its ends vis-à-vis another nation by peaceful means or whether it had to resort to military force to achieve them, for the risks involved in the resort to military force were generally not out of proportion to the ends sought. Great ends justified great risks, since the risks were generally not so great as to obviate the ends. Yet all-out nuclear war, likely to destroy all belligerents and thus to eliminate the very distinction between victor and vanquished, is a completely irrational undertaking. No possible end can justify it; it is an instrument of mass murder and mass suicide.

Two Modern Dilemmas.—International relations, then, were faced with two interconnected dilemmas upon the solution of which depended the survival of western civilization and perhaps of mankind itself. The first dilemma consisted in the contrast between the technological unification of the world and the parochial moral commitments and political institutions of the age. Moral commitments and political institutions, dating from an age which modern technology had left behind, had not kept pace with technological achievements and, hence, were incapable of controlling their destructive potentialities. The second dilemma consisted in the contrast between the need of nations to support their interests by resort to violence and the irrationality of resort to nuclear arms. If a nation cannot resort to nuclear weapons without risking its own destruction, how can it support its interests in a world of sovereign nations which is ruled by violence as the last resort?

These two dilemmas put into question the very survival of the existing system of international relations. The first dilemma suggests a higher principle of international organization, transcending the nation-state, in the form either of a universal organization, such as the United Nations, which would minimize threats to international peace, or of regional organizations, such as the European communities or a projected Atlantic union, which would eliminate local threats to peace and facilitate the rational use of regional resources. The second dilemma suggests the abolition of international relations itself through the merger of all national sovereignties into one world state which would have a monopoly of the most destructive instruments of violence. Both kinds of solutions are supported by the awareness of the unity of mankind, underlying the inevitable fragmentation of international relations. However inarticulate and submerged, this awareness never completely disappeared even in the heyday of nationalism, and it has been sharpened by the threat of nuclear destruction facing all mankind. These solutions are also supported by the longing to give that unity a viable political form, a longing which has time and again endeavoured through theoretical schemes and practical measures to transform international relations into a supranational political order. This longing, in times past mainly a spiritual or humanitarian impulse, was in the nuclear age greatly strengthened by the desire for self-preservation, innate in all men.

INTERNATIONAL TRADE: *see* TRADE, INTERNATIONAL; EXPORTS; IMPORTING; INTERNATIONAL PAYMENTS; COMMERCE, HISTORY OF; TARIFF.

INTERNATIONAL TRADE ASSOCIATIONS AND CONGRESSES. The 19th century, though often regarded as the age of nationalism, nevertheless was characterized by the growth of private international organizations covering almost every branch of human activity and expressing the supranational extent of modern interests. These organizations multiplied at an even faster pace in the 20th century, about 1,254 being recognized by the Union of International Associations in 1960, as compared with 185 in the first comprehensive account in 1907.

This article is limited to permanent international associations (those representing nationals of more than one country and having a more or less continuing central office or secretariat) in the fields of commerce, industry, finance, transport, communications, agriculture and ancillary professions. Official organizations founded by intergovernmental agreement are excluded, as are also profit-making international groups, such as Standard Oil and the Havas News agency; it is more appropriate to classify the latter as unified business concerns operating in more than one country than as federal associations of national economic interests.

Growth and General Characteristics.—The 19th-century international fairs beginning with the Great exhibition of 1851 in London provided the occasion for the first international associations. Exhibitors at these meetings not only saw the value of more permanent collaboration, but they were also able to secure such official international agreements to protect their rights when abroad as the International Union for the Protection of Industrial Property of 1883 and the Berne copyright convention and union of 1886. Some impression of the rate of growth of private organizations can be derived from statistics (World Peace Foundation, "Pamphlet Series," vol. vi, no. 6 [1916]), which show that, while there were 18 meetings of these bodies in 1850–59, the number had increased to 139 in 1870–79 and to 985 in 1900–09, and that 458 international assemblies met in 1910–14. Corresponding figures for 1919–39 are lacking, but it was reliably estimated that in the early 1930s between 200 and 250 of these meetings took place annually. The evidence from post-1945 experience suggests that these associations possess a remarkable capacity to survive war and political changes. By 1960, for example, 334 private international organizations had passed the rigorous tests of admission to consultative status with the United Nations Economic and Social council.

As for the interests in which international organization has proved most active and viable, there is a difference between those activities, such as railway transport, which have an obvious international significance, and those, such as agriculture, in which national organization is itself weak or which have a predominantly local area of activity. On the whole, agricultural producers' associations have been ephemeral or regional, or confined to secondary or subsidiary agrarian pursuits. It is notable here that the development of official international institutions influenced the relative growth of various types of private organizations; the International Labour organization (ILO), for example, prompted the formation of the International Organization of Employers for the better co-ordination of the employers' point of view. Another interesting form of nongovernmental organization intermediary between the two extremes just mentioned is that dealing with international standards for industry and commerce; the International Organization for Standardization is conspicuous here. Further, since some of the most typical activities of nongovernmental organizations are joint inquiries into questions of common interest to the membership, it is not surprising that professional organizations among actuaries, accountants, architects and engi-

neers have had an important part to play.

The spontaneous growth of these organizations has naturally meant extreme variety in structure and function. Some have highly complex constitutions, with considerable incomes and authority over their members. Others are little more than annual meetings at an accessible centre for an informal exchange of views about trade prospects, with little in the way of binding understandings being reached. Generally members are not individuals but national associations, though hybrid forms exist. A convenient form of classification is the distinction between organizations which are wholly private and those in which there is some official component. The International Institute of Refrigeration is indisputably an official body; it was founded in 1920 by a convention between governments and is governed by a general conference composed of government representatives. But where an organization, such as the International Federation for Housing and Town Planning, is directed by a council having at one time a majority of delegates from official agencies and at another a majority of nongovernment representatives, the case is more difficult to determine. In the marginal zone between the private and the semi-official. limits of the former can probably be best discovered through scrutiny of the functioning of the organization's services.

The functions and activities of international nongovernmental organizations are not essentially different from those of their national correlatives. They are intended to further the special interests of members by providing permanent machinery for exchanging views and pooling information, for public relations on an international scale, for joint studies and research, for the elaboration of standards and metric systems to facilitate international commerce, and for bringing pressure to bear upon governments. Wherever a national business or calling has something to gain by links with its opposite numbers abroad, the basis for international organization exists. Sometimes the sectional character of these groups has been masked by pacifist or internationalist ideals, but in many instances the fact that technical collaboration between private national groups seemed to be more fruitful than negotiation at the diplomatic level genuinely gave rise to the belief that in this lay the road to ultimate world order.

Business and Commerce.—The colossus among commercial organizations is the International Chamber of Commerce (I.C.C.), with a history as a forum for business interests extending back to 1869, though it was not constituted as a permanent association until 1920. The I.C.C. announced itself as a "confederation of the main economic forces of the countries included in its membership"; these forces are: (a) organization members, that is, national and local associations grouped for this purpose into national committees, which operated in about 40 different countries in the early 1960s, and (b) associate members, consisting of individual businessmen, firms and corporations in countries where no national committee is functioning. A regional group, the Commission on Asian and Far Eastern affairs, serves national committees in southern Asia and Japan. There is a supreme policy-making organ, the biennial congress, a permanent council representing each national committee, and an executive committee elected by the council. Some 40 commissions and committees for technical work handle the four main departments of the I.C.C.'s activities: economic policy, distribution and advertising, transport and communications, law and commercial practice. A court of arbitration adjudicates disputes arising between businessmen of different countries; there is also a council to determine what constitutes unfair practice in international advertising, and a central information bureau. The I.C.C. is commonly recognized as having exercised an appreciable influence on government policy during the period between the two world wars, especially in war debt and reparation issues; it is also said to have contributed much to the establishment of the International Bank for Reconstruction and Development and of the International Monetary fund of the United Nations.

The analogous body for co-operative organizations, the International Co-operative alliance (I.C.A.), sprang from exchanges between the British and French co-operative congresses in the 1880s, though the first international congress that formally created the alliance did not meet until 1895. The I.C.A. has among its aims "to be the universal representative of co-operative organizations of all types" and "to propagate co-operative principles and methods throughout the world." Its members by 1960 included 153,000,000 people grouped in national, regional and local co-operative organizations in 47 countries; 34,000,000 of these lived in the Soviet Union. Its structure closely resembles that of the I.C.C., its chief policy-making organ being a triennial congress. Some indication of the scope of the alliance's interests and activities is provided by the fact that at the Lausanne congress, which met in 1960, there were auxiliary conferences dealing with international co-operative trade, banking, insurance, co-operative agriculture, workers' co-operative production, co-operative press and education, and the role of co-operation in housing. The 1954 development fund for assisting underdeveloped countries is a special I.C.A. enterprise.

In the business field are many organizations much smaller than these two giants. Typical of the wide variety of these groups are, in order of their foundation, the Union of International Fairs, started in 1925 for the improved co-ordination of facilities for international fairs offered by public authorities; the International Association of Department Stores, a European organization that in 1928 became responsible for research on management and distribution; and the International Office for Motor Trades and Repairs, with its headquarters at The Hague and members in more than a score of countries. The advertised objects of the latter organization are to distribute information on the sale, repair and service of motor vehicles and to encourage ethical business codes with a view to their adoption internationally.

Manufacturing Industry.—International organization in the manufacturing trades has generally been stronger in the secondary than in the basic industries and in the production of those commodities that play a large part in international trade. One exception to this is the International Organization of Employers (formerly Industrial Employers), which was founded in 1919 with national federations of employers as its members in order to ensure permanent liaison between employers' representatives at conferences of the ILO. The organization is, however, more of a defensive reaction to international labour pressures than a spontaneous industrial organization.

Among the secondary trades, the food, hotel management, fuel and power, building and light industries are well represented. The International Office of Cocoa and Chocolate, which functions in Brussels, Belg., was founded by cocoa and chocolate manufacturers in 1930 and studies all questions relating to the cultivation of cocoa and subsequent manufacturing processes. The International Federation of Meat Traders' associations met annually in general assembly for similar objects beginning in 1946; it is wholly a west European organization. The European Brewery convention, established in 1947, and the European Coffee bureau, created in 1959 to study and disseminate knowledge of coffee, are other examples of the extent and variety of these associations in the food industries. The International Hotel association in 1946 took over the functions of the International Hotelmen's association and of the International Hotel alliance, which were founded in 1869 and 1921, respectively, with the object of federating all the hotel associations of the world in order to formulate a common policy on international tourist traffic. Finally in this group may be mentioned the extensive and active organizations in the fuel and power industries. The World Power conference, representing national committees in more than 50 countries, normally meets in plenary session once every six years in order to study existing resources of hydroelectric power, coal, oil and other fuels and minerals, and to explore the possibility of their more efficient utilization. It has a permanent central office managed by an executive council and is powerfully supported by such organizations as the International Electrotechnical commission (founded 1906), which facilitates the "co-ordination and unification of national electrotechnical standards not already covered by the statutes of any other recognized international organization" among more than 30 countries of industrial importance; the International Union of Producers and Distributors of Electrical Energy (founded 1925), a

professional organization for the study of the production and transmission of electrical energy; and the International Conference on Large Electric Systems (founded 1921), which also has within its purview the study of all technical questions concerning electrical energy.

Textiles are the foremost internationally organized trade among the group with an important interest in the world market. The International Wool secretariat (1937) originally represented the wool boards of Australia, New Zealand and South Africa with their branches in Europe, India and Pakistan, but in 1949 the Wool Bureau, Inc., representing wool producers in North America, was admitted to associate membership. The International Wool secretariat defines its purposes boldly as the promotion of the interests of the producers and users of wool everywhere. The manufacture of wool and allied fibres is represented by the International Wool Textile organization, which arose in 1929 from arbitration agreements between the chambers of commerce of Bradford, Eng., and Roubaix Tourcoing, France, and gradually extended in membership and scope until by 1960 it covered wool organizations in 14 countries in Europe and 7 elsewhere, including Australia and Japan, and represented the "production, commerce and industry of wool textiles in all branches of international economic activity." Similar organizations have been promoted for cotton and silk: the International Federation of Master Cotton Spinners' and Manufacturers' Associations (1904), renamed the International Federation of Cotton and Allied Textile Industries in 1954, represents producer organizations in Europe, India and Egypt and offers such important services to its members as the arbitration of international disputes and, from 1922, an annual survey of the state of the U.S. cotton crop; and the International Silk association (1949) maintains liaison between representative bodies in all parts of the world. Later stages in clothing manufacture are represented by the International Rainwear council and the International Committee for Dyeing and Cleaning, among others; the former dates from 1959 and covers a number of European countries and the U.S., while the latter, founded in Paris in 1950, is an association of national federations, chiefly in Europe.

Apart from textiles and clothing, motors and railroad rolling stock have formed the most important manufacturing trades for international organization. The International Permanent Bureau of Motor Manufacturers succeeded in 1919 the pre-World War I International Union of Motor Manufacturers; its constituent bodies comprise national associations in several European countries and in the U.S. The International Association of Rolling Stock Builders, founded in Paris in 1930, was originally a cartel for the allocation of the export market; its purpose in 1934 was re-defined more generally as to "defend on the international level the general interests of the rolling stock builders' industry." It has a European membership only.

Finance.—Notwithstanding the essentially international character of modern finance, nongovernmental organizations dealing with financial business are relatively few, since international clearings between the central banks of the different countries are generally officially regulated. The most important private organization in this field is the International Credit Insurance association, with its headquarters in Zürich, Switz.; it was founded in 1946 to carry on a previous organization of the same name founded in Paris in 1928. The association is a clearing centre for leading insurance companies in Europe, Mexico, Venezuela and the Republic of South Africa. Its evidence bureau in Amsterdam, Neth., provides different firms with opportunities for joint consultation if they are approached to insure the same risks. A similar financial organization is the International Thrift institute, an association of savings banks in European, Asian and American countries, which was formed in 1925 and was reorganized in 1948 when its office was moved from Milan, Italy, to Amsterdam. The Thrift institute's aims, which include helping savings banks to "enhance their influence and prestige internationally," suitably introduce another class of organizations having an interest in finance but with some financial doctrine or policy to advertise: the International Centre of Research and Information on Collective Economy, the International Interchange committee and the International Union for Land Value Taxation and Free Trade are interesting specimens of these.

Communications.—The international agreements into which communications have entered have generally been diplomatic instruments, such as the convention of 1874 which created the Universal Postal union. In radio broadcasting, however, it was unofficial effort to eliminate the overlapping use of wave lengths that led to official intervention. The "plan of Geneva" of the unofficial International Broadcasting union, founded in 1925 for the rational allocation of European wave bands, became the basis of the intergovernmental convention adopted at Lucerne, Switz., in 1933. Thereafter the union through its technical observation post at Brussels verified daily the accuracy with which the various stations maintained their assigned wave lengths, and assisted the League of Nations Intellectual Co-operation organization in promoting international exchanges of broadcasting material. In 1950 the union was superseded by the European Broadcasting union (E.B.U.), which in the 1960s consisted of "active" broadcasting organizations and national associations of broadcasting bodies situated in 25 countries and "associates" in 14 countries. Through an annual general assembly and an administrative council, the union works to "safeguard in all fields the interests of broadcasting organizations that have adhered to the statutes, and establish links with others"; its technical centre in Brussels maintains the frequency control of the period before World War II and studies all questions of technical interest.

Amateur radio is represented by the International Amateur Radio union (1925), which seeks to promote and co-ordinate two-way radio communication between the amateurs of various countries. For broadcasting in the Americas the Inter-American Association of Broadcasters, created by a radio conference at Mexico City in 1946, has for its objects the promotion of co-operation between radio stations in the public interest and the effective representation of broadcasting organizations at the national and international level. To improve wireless services at sea, the International Radio-Maritime committee was set up in 1928 at San Sebastian, Spain. After its reconstruction in Brussels in 1947 its effective members became radio organizations in Atlantic and Mediterranean countries. The committee's scientific centre prevents interference between ships' radios much as the E.B.U. technical centre prevents interference between stations on land, and its technical commission looks after the interests of maritime radio at national and international conferences.

Transport.—Among the international associations for transport, as for communications, it is not always easy to distinguish between private and official bodies; this is particularly so in railway transport, since the most important railway systems in Europe are state managed. The organizations cited here are those which nevertheless are open to private companies, provided these be of international importance and have not been established by agreement between governments. The International Union of Railways, with its headquarters in Paris, where it was founded in 1922, is composed of railway administrations with at least 1,000 route km. (621 mi.) of line and having traffic relations with each other within and outside Europe; it seeks to unify and improve the construction and operation of railways engaged in international traffic. Its annual general assembly controls a system of standing committees dealing with the standardization of rolling stock, the modernization of equipment, and international timetables. A somewhat similar organization is the International Railway Congress association, first established in 1884; its membership of state railway administrations and private companies in more than 60 countries is geographically more extensive than the International Union of Railways, and it aims at the more general objective of "promoting railway progress by holding periodical congresses and by publications." Similar work is carried on by the Pan American Railway Congress association, founded in 1906. This body is composed both of public and private companies and works through a system of committees toward the unification and modernization of railway transport and the reform of legislation affecting railways. Efforts to reduce inconvenience caused by transfer from one national railway network to another were made through the

European Passenger Time-Table conference (1923). This is in the main an official body but includes private delegates and works on a consultative basis with the International Union of Railways. The latter is also associated with the International (Railway) Wagon union, founded in 1921 to ensure the application of the *Regolamento Internazionale Veicoli,* which provides for the reciprocal use of railway cars in international traffic by its member railway administrations, most of which are European.

Some international organizations for shipping are more like profit-making concerns, such as the shipping conferences that grew up in the late 19th century to eliminate price cutting. The Baltic and International Maritime conference, however, first founded under another name in 1905, provides for mutual consultation in all matters affecting the shipping industry, for defining and circulating news of "objectionable practices" among its members and for approving documents for the use of shipowners. Its members are in three classes—owners, ship brokers and federations of owners' and protecting associations in all parts of the world. An even more general association of shipowners is the International Chamber of Shipping (I.C.S.), founded in 1921 as the International Shipping conference, a federation of national associations of private owners. Wages and conditions of labour at sea are within the purview of the International Shipping Federation Ltd., having a membership similar to that of the I.C.S.; it was dealing with strikes in the industry before 1914 but was given a permanent form with the establishment of ILO. The important role in shipping of international maritime law and maritime insurance is indicated by the International Maritime committee, a federated law society that began to promote intergovernmental maritime conventions in 1897, and the International Union of Marine Insurance, a federal association of insurance and underwriter groups; this was established in 1874 and reorganized in 1946.

The obvious benefits of international connections for tourists is reflected in the associations that grew up for motor transport, especially in connection with sport and recreation. The International Automobile federation is a post-World War II form of the old International Association of Recognized Automobile clubs, which had existed since before World War I. It serves motoring clubs in almost every country and is closely associated with the International Touring alliance, which was founded in 1893 to bring into touch with each other the various national touring groups. Among organizations for road transport as an industry are the Permanent International Association of Road congresses (1909), a semiofficial body concerned with the general improvement of world road conditions, and the International Union of Public Transport (1885), a mixed public and private body dealing principally with problems of urban transport.

When the official conference met in Chicago, Ill., in 1944 to approve the convention establishing the International Civil Aviation organization (1947), the airline operators attached to the national delegations met to reconstruct the old private International Air Traffic association, founded at the end of World War I. The new body, the International Air Transport association, an agency for consultation between airline companies in many countries, claims to speak for 90% of the world's scheduled air traffic; it acts as a central bank of information on all subjects and supplies technical advice to its members. The International Aeronautical federation, established by seven European governments and the United States in 1905, has for its object the promotion of world aeronautics, including private flying, in all its forms.

Agriculture.—Since organization among sectional interests is usually as strong internationally as it is nationally, agriculture did not produce an abundance of private international associations. While the functions and assets of the official International Institute of Agriculture (1905) were transferred to the Food and Agriculture Organization of the United Nations (FAO) in 1946, the voluntary organization, the International Commission of Agriculture (I.C.A.), though dating from 1889, tended to lack official encouragement; its chief function was to bring together representatives of its constituent organizations in biennial congresses to contribute concertedly to the basic knowledge of every branch of agriculture. The I.C.A. is said to have influenced the principles of agricultural policy adopted by the 1933 World Economic conference in London and the bilateral treaties on exchange of produce concluded by certain European countries in the 1930s. The commission was reorganized in 1948 as the European Confederation of Agriculture; it speaks for agricultural associations in many different countries in Europe and the Mediterranean basin. It claims to protect independent family farming and all forms of mutual aid between people employed in farming.

Representations to official international conferences on behalf of European farming are made by the confederation, the organization speaking for the agricultural world as a whole being the International Federation of Agricultural Producers, which was created at a London conference of farm organizations in 1946. This represents general farm and agricultural co-operative organizations in all parts of the world and meets in council once every two years.

Some farm organizations are specialized by product, such as the World's Poultry Science association (1912), the International Olive Growers federation (1934) and the International Dairy federation (1903). Some are regional: the Liaison Committee of Mediterranean Citrus Fruit Culture (1949); the American Society of Agricultural Sciences (1940); and the European and Mediterranean Plant Protection organization (1951). Certain associations, such as the International Confederation for Agricultural Credit (1932), link farming with other interests.

Professional.—Activities deriving special benefits from international co-operation are those which rely upon research or standardized methods for their efficiency. Thus professions serving trade and industry are relatively well organized internationally. The International Statistical institute (1885), with its highly qualified and geographically well-distributed membership, is devoted to the development and improvement of statistical methods; the International Conference of Agricultural Economists (1929) publishes records of current progress in agricultural economics; among others, the Permanent Committee of International Congresses of Actuaries (1889) links together actuaries' associations in different countries. Similar associations for engineering include the International Association for Bridge and Structural Engineering (1929) and the Union of International Engineering Organizations, which originated in an engineering conference convened by the United Nations Educational, Scientific and Cultural organization (UNESCO) in 1950. One of the most useful of these professional bodies is the International Organization for Standardization, founded in 1946 on the basis of an older organization dating back to 1926: this is a federation of national standardizing bodies seeking through the adoption of universal standards to facilitate the world exchange of goods and services.

Relations With Intergovernmental Organizations.—*The League of Nations.*—Art. XXIV of the covenant excluded international bureaus other than those "already established by general treaties" from the provision placing existing international organizations under the aegis of the League. The private organizations, however, were not without influence on national policies within the League. Representatives of important organizations were sometimes included in national delegations to the assembly, and at international conferences under League auspices nongovernmental groups were often allowed to participate in a consultative capacity: the International Chamber of Commerce played an important part in the World Economic conference of 1927 and in the League conference on international trade restrictions in 1928. These associations were active also in the work of the relevant committees and ancillary organs attached to the League. Eight of them, for example, were invited to send representatives to sessions of the Consultative Technical Commission on Communications and Transit, and not only did the ILO constitution presuppose active unofficial organizations but the organization much depended upon them for the carrying out of ratified conventions.

The United Nations.—The UN Conference on International Organization at San Francisco, Calif., in 1945 decided not to admit representatives of private international organizations in a consultative capacity, though consultants from 50 private national groups served unofficially in the U.S. delegation. The charter issuing from the conference, however, gave the first recognition in any multi-

lateral agreement to these bodies; art. 71 permits the Economic and Social council to make arrangements for consultation with nongovernmental organizations, with which it may negotiate directly. These arrangements were put into effect in June 1946 and reviewed at the council's tenth session (Feb. 1950), which adopted a resolution setting out the present form of consultation.

A nongovernmental organization applying for consultative status with the council must satisfy certain conditions; *inter alia* it must deal with matters within the competence of the council; its aims and purposes should conform with those of the UN, which it must undertake to support and publicize; it must be of recognized standing and represent a substantial proportion of the organized persons in its field. Organizations having "a basic interest in most of the activities of the Council" and "closely linked with the economic or social life of the areas which they represent" are admitted to category A consultative status. Category B includes those which have a special competence or are concerned specifically with only a few of the fields of activity covered by the council. In 1960, 119 organizations were included in category B, as compared with 10 in category A. Other organizations that "have a significant contribution to make to the work of the Council" may be entered by the secretary-general in a register established for the purpose. In general, organizations in all three categories may attend the council as observers and submit written statements relative to the work of the council. Category A organizations may also have items of special interest inserted in the provisional agenda of the council, which they may address on such items. A special committee of the council determines the manner in which consultation in the three categories is to be effected.

These arrangements provided a model for similar relations between the UN specialized agencies and the private organizations. Three of the groups mentioned above, the International Chamber of Commerce, the International Co-operative alliance, and the International Federation of Agricultural Producers, acquired consultative status with the FAO. The International Civil Aviation organization by a resolution of June 1947 authorized its council to make suitable arrangements with private international bodies whose activities affect international civil aviation. Art. XI (4) of the constitution of UNESCO provides for co-operation with international organizations of this type in its field. The treaty of the European Coal and Steel community makes provision in art. XLVI and XLVIII for consultation with private organizations in its field of activity. *See* also INTERNATIONAL ORGANIZATIONS.

INTERPOL: *see* INTERNATIONAL CRIMINAL POLICE ORGANIZATION.

INTERPOLATION AND EXTRAPOLATION are processes for finding additional terms of sequences on the basis of terms that are already given. For instance, the ordered set of four-place values of the function $u = \log_{10} x$, shown in Table I, may be regarded as terms of a sequence for which the computation of the logarithm of any additional value of x, say $x = c$, may be required.

In such cases, if c lies between the smallest and the largest of the given values of x, the process is called interpolation; if c lies beyond these limits, the term extrapolation is appropriate. Interpolation is often used to include both, and will be so used here when convenient. More general situations, in which u is a function of two or more variables, will not be considered in this discussion.

The term interpolation refers most commonly to polynomial interpolation. In the one-variable case, where the function $u(x)$ is known for a set of $n + 1$ values of x, there is only one polynomial $y(x)$ of degree n, of the form $y(x) = A_0x^n + A_1x^{n-1} + \ldots + A_{n-1}x + A_n$ that agrees with $u(x)$ at those $n + 1$ points. Polynomial interpolation or extrapolation based on such data usually consists of approximating the unknown value of $u(x)$ when $x = c$ by the value of $y(x)$ when $x = c$. Available formulas for this purpose differ with respect to the form in which the approximating polynomial is written, but generally afford identical results from the same data.

Usually the tabular values of u correspond to successive values of x that differ by a constant increment h (as in Table I where $h = .01$) and a value of u is required for a specified value of x. The reverse process, in which a value of x is sought for a given value of u, may be described as inverse interpolation or extrapolation to distinguish it from the usual direct process of finding u from x.

DIRECT INTERPOLATION (EQUAL INTERVALS)

Differences and Difference Tables.—In such cases as Table I, if one of the tabular values of x (not necessarily the first one) is denoted by x_0, it is convenient to write $x_m = x_0 + mh$, so that the tabular values of x are $\ldots, x_{-1}, x_0, x_1, x_2, \ldots$, and to use the notation $\ldots, u_{-1}, u_0, u_1, u_2, \ldots$ for the corresponding values of u. Suppose that the value u_s is required in correspondence with $x_s = x_0 + sh$, where s is the difference between x_s and x_0 in terms of the increment h, then

$$s = \frac{x_s - x_0}{h} \tag{1}$$

One class of methods for polynomial interpolation in such a table involves the formation of a difference table in which the column of

TABLE I

x	$u = \log x$	1st difference
...	.	.
2.70	.4314	16
2.71	.4330	16
2.72	.4346	16
2.73	.4362	16
2.74	.4378	15
2.75	.4393	.
...	...	

u values is followed by columns of successive differences. Differences between adjacent u's are first differences; differences between adjacent first differences are second differences, and so on. Three notations are in common use for distinguishing differences. In the forward-difference (advancing-difference) system, $u_1 - u_0$ is regarded as the first difference of u_0 and is written as Δu_0; in the backward-difference (receding-difference) system, the same difference is associated instead with u_1 and is written as ∇u_1. In the central-difference system, which will be used here, the subscript associated with a difference is the average of the two parent subscripts and the first difference $u_1 - u_0$ is written as $\delta u_{\frac{1}{2}}$. The second difference $(u_2 - u_1) - (u_1 - u_0) = u_2 - 2u_1 + u_0$ is written $\Delta u_1 - \Delta u_0 = \Delta^2 u_0$ (forward), $\nabla u_2 - \nabla u_1 = \nabla^2 u_2$ (backward) and $\delta u_{\frac{1}{2}} - \delta u_{-\frac{1}{2}} = \delta^2 u_1$ (central) and so on.

In the central-difference notation, a portion of a difference table would correspond to the notation of Table II, where each entry in a difference column is the difference between its two left-hand neighbours. Usually the numerical entries in the difference columns are expressed as integers, in units of the last decimal place retained in the u's, as in Tables I, III and IV.

Linear Interpolation.—The simplest and best known method of polynomial interpolation is based upon two successive tabular entries, say $u_0 = u(x_0)$ and $u_1 = u(x_1)$, with $u(x)$ approximated by the linear function (first-degree polynomial) that agrees with $u(x)$ when $x = x_0$ and when $x = x_1$. For a linear function $y(x)$, the change in y is proportional to the change in x and, if $y_s = y(x_s)$, then $y_s - u_0 = s(u_1 - u_0) = s\delta u_{\frac{1}{2}}$. Thus, the result of approxi-

TABLE II

x	u	Differences			
		1st	2nd	3rd	4th
.	.	.	.	.	.
x_{-2}	u_{-2}				
		$\delta u_{-\frac{1}{2}}$			
x_{-1}	u_{-1}		$\delta^2 u_{-1}$		
		$\delta u_{\frac{1}{2}}$	$\delta^2 u_0$	$\delta^3 u_{\frac{1}{2}}$	$\delta^4 u_0$
x_0	u_0			$\delta^3 u_{\frac{1}{2}}$	
		$\delta u_{\frac{1}{2}}$	$\delta^2 u_1$		
x_1	u_1				
		$\delta u_{\frac{3}{2}}$			
x_2	u_2				
.	.	.	.	.	.

mating u_s by y_s is the formula for linear interpolation

$$u_s \approx u_0 + s\delta u_{\frac{1}{2}} \tag{2}$$

It is desirable that x_s fall between x_0 and x_1; otherwise, the process is one of extrapolation, which generally produces larger errors than interpolation does.

In Table I, the fact that the first differences are nearly constant suggests the use of (2), at least for x_s between 2.70 and 2.75. For example, $\log 2.7242 \approx .4346 + .42(.0016) = .4346 + .000672 = .435272$, which is .4353 rounded to four places. If this result were to be used for further calculation, it would be desirable to carry along one or two extra figures (perhaps writing $\log 2.7242 \approx .4352_7$) and to round the final result appropriately instead. Similarly, $\log 2.733 \approx .4362 + .3(.0016) = .4366_8$, $\log 2.754 \approx .4378 + 1.4(.0015) = .4399_0$ and $\log 2.697 \approx .4314 + (-3)\ (.0016) = .4309_2$. Note that the last two calculations are extrapolations.

Possible sources of error in linear interpolation and extrapolation include the inherited error E_I in the calculated value of u_s arising from inaccuracies in the given entries u_0 and u_1; the roundoff error E_R introduced if the calculated value of u_s is rounded; and the truncation error E_T that results from representing $u(x)$ as a linear function when (2) is used. For linear interpolation, where $0 < s < 1$ in (2), the inherited error cannot exceed the larger of the inherent errors in u_0 and u_1; but, for linear extrapolation there is no assurance of this. Clearly, the roundoff error never can exceed five units in the first omitted decimal place. The error E_T is harder to analyze and control. Generally it is assumed that the increment h is small enough to make this truncation error negligible, unless there is a warning to the contrary. Appreciable second differences provide such a warning; but, although small second differences are reassuring, they do not always guarantee the propriety of linear interpolation.

The four values interpolated above correspond, respectively, to the true five-place values .43524, .43664, .43996 and .43088, and their five-place approximations differ from the true values by 3, 4, 6 and 4 units in the fifth place. These deviations resulted almost completely from inherent errors (which could be as large as 5 units in the fifth place in consequence of the given data having been rounded to four places) since it can be proved that the truncation error here could not exceed one unit in the sixth place. The rounded four-place approximations (.4353, .4367, .4399 and .4309) differ from the true rounded four-place values (.4352, .4366, .4400 and .4309) by not more than one unit in the fourth place. Although the extrapolations here were about as accurate as the interpolations, such a result is not generally to be expected.

		147	
3.0	.4771		
.	.	.	.

Although the first differences in Table I are nearly constant, this does not mean that the second differences of u are exactly zero. It means only that in working to four decimal places the second differences that would occur in Table I are negligible. That they are not in fact zero can be shown either by taking more nearly correct values, as in Table III, or by taking values of x at a greater interval, as in Table IV. Similarly, differences of higher order could be detected.

Sequences of differences may present irregularities when the tabulated entries are not exact, even though those entries be correctly rounded to the places retained. Thus in Table I the difference 15 arose because the correctly rounded entry for log 2.74 is too large while that for 2.75 is too small, as may be seen from Table III. A similar explanation applies to the entry −57 in Table III.

Interpolation With Higher Differences.—When polynomial interpolation is based on values of $u(x)$ at $n + 1$ equally spaced points, generalizations of formula (2) may be used that involve the first n differences of u. One of these (associated with the names of Newton and Gauss) is of the form

$$u_s \approx u_0 + s\delta u_{\frac{1}{2}} + \frac{s(s-1)}{2!}\delta^2 u_0 + \frac{s(s^2-1^2)}{3!}\delta^3 u_{\frac{1}{2}} + \frac{s(s^2-1^2)(s-2)}{4!}\delta^4 u_0 + \ldots \tag{3}$$

The last term is $s(s^2-1^2)\ldots[s^2-\frac{1}{4}(n-2)^2](s-\frac{1}{2}n)\delta^n u_0/n!$ when n is even, and $s(s^2-1^2)\ldots[s^2-\frac{1}{4}(n-1)^2]\delta^n u_{\frac{1}{2}}/n!$ when n is odd. When $n = 1$, formula (3) reduces to (2); when $n = 2$, formula (3) corresponds to approximating $u(x)$ by the second-degree polynomial $y(x)$ which agrees with $u(x)$ when $x = x_0$, x_1 and x_{-1}. When $n = 3$, the approximation $y(x)$ is the third-degree polynomial that agrees with $u(x)$ when $x = x_0$, x_1, x_{-1} and x_2, and so on.

It is desirable to select an x_0 (from among the x values for which requisite differences are available) that is nearest the value of x for which interpolation is to be effected. Tables of the coefficient functions in such formulas as (3) can be found in the literature.

Using (3) in Table III, the interpolated value is found to be

$$\log 2.7242 \approx .4345689 + .42(.0015937) + \frac{(.42)(-.58)}{2}(-.0000059) = .4352389_7$$

and the extrapolated value

$$\log 2.754 \approx .4377506 + 1.4(.0015821) + \frac{(1.4)(.4)}{2}(-.0000059) = .4399638_9$$

These may be compared with the respective rounded true values .4352390 and .4399639.

Everett's Formula.—Many published tables of functions provide second differences (and perhaps also fourth differences) and guarantee that polynomial interpolation based on Everett's formula, retaining the differences provided, will yield results within specified error tolerances. The formula is of the form

$$u_s \approx (1-s)u_0 - a_1(s)\delta^2 u_0 + a_2(s)\delta^4 u_0 + su_1 - b_1(s)\delta^2 u_1 + b_2(s)\delta^4 u_1 \tag{4}$$

where the coefficient functions are defined by the equations

$$a_1(s) = \frac{1}{6}s(1-s)(2-s)\quad a_2(s) = \frac{1}{120}(1+s)s(1-s)(2-s)(3-s)$$

$$b_1(s) = \frac{1}{6}(1+s)s(1-s)\quad b_2(s) = \frac{1}{120}(2+s)(1+s)s(1-s)(2-s) \tag{5}$$

and are themselves tabulated in many sources. If the two fourth-difference terms are ignored, formula (4) yields the same result as (3) when third differences are retained; if the δ^4 terms are used in (4), the result is equivalent to (3) when fifth differences are retained. However, no differences of odd order are needed in (4). It is desirable for interpolation to number the tabular entries so

that $-\frac{1}{2} \leq s \leq \frac{1}{2}$ when possible, and to make $|s|$ as small as possible in any case.

Table V, for example, yields the interpolated value $\log 2.84 \approx (.6)(.4471580) - (.0640)(-.0005542) + (.0116)(-.0000046) + (.4)(.4623980) - (.0560)(-.0005167) + (.0108)(-.0000037) = .4533183_1$ when fourth differences are retained in (4). The necessary coefficients may be read from a table such as Table VI.

TABLE V

x	$\log x$	δ^2	δ^4
.	.	.	.
2.8	.4471580	−5542	−46
2.9	.4623980	−5167	−37
3.0	4771213	−4829	−30
.	.	.	.

TABLE VI

s	a_1	a_2	b_1	b_2
.	.	.	.	.
.3	.0595	.0104	.0455	.0089
.4	.0640	.0116	.0560	.0108
.5	.0625	.0117	.0625	.0117
.	.	.	.	.

with $s = .4$. The true seven-place value is .4533183. Omitting fourth differences in (4) gives $.453318_{40}$, while linear interpolation gives $.453_{25400}$.

DIRECT INTERPOLATION (UNEQUAL INTERVALS)

Lagrange's Formula.—When consecutive tabular values of x are unequally spaced, formulas for polynomial interpolation can be used that generalize those preceding by introducing so-called divided differences. The relevant definitions and formulas will not be detailed here.

Alternatively, Lagrange's formula, which expresses the approximating polynomial directly in terms of u (in place of differences or divided differences), is applicable whether or not the tabular values of x are equally spaced, and can be written in the form

$$u(x) \approx \frac{(x - x_1)(x - x_2) \dots (x - x_n)}{(x_0 - x_1)(x_0 - x_2) \dots (x_0 - x_n)} u(x_0) + \frac{(x - x_0)(x - x_2) \dots (x - x_n)}{(x_1 - x_0)(x_1 - x_2) \dots (x_1 - x_n)} u(x_1) + \dots + \frac{(x - x_0)(x - x_1) \dots (x - x_{n-1})}{(x_n - x_0)(x_n - x_1) \dots (x_n - x_{n-1})} u(x_n) \quad (6)$$

when the calculation is to be based on values of u which correspond to $n + 1$ values of x.

When the tabular values of x are equally spaced, (6) yields results identical with those of (3) after an appropriate renumbering of the entries. Differencing is avoided in such cases with tables of appropriate Lagrange coefficient functions. On the other hand, without a difference table the possibility of gaining useful information from the size and regularity of the entries in successive columns is lost.

To illustrate the use of (6) with unequal spacings, suppose that only the three four-place values $\log 2.70 = .4314$, $\log 2.72 = .4346$ and $\log 2.73 = .4362$ are available. Here (6) becomes

$$\log x \approx .4314 \frac{(x - 2.72)(x - 2.73)}{(.02)(.03)} - .4346 \frac{(x - 2.70)(x - 2.73)}{(.02)(.01)} + .4362 \frac{(x - 2.70)(x - 2.72)}{(.03)(.01)}$$

the right-hand member being the second-degree polynomial which agrees with $\log x$ (to four places) at the three relevant points. As an example of interpolation, $\log 2.71 \approx \frac{1}{2}(.4314) + 1(.4346) - \frac{1}{2}(.4362) = .4330$. In an extrapolation problem, $\log 2.74 \approx \frac{3}{2}(.4314) - 2(.4346) + \frac{5}{2}(.4362) = .4378$. Both values are correct to the four places given.

INVERSE INTERPOLATION

Reversion of Tables.—When inverse interpolation is to be effected, the roles of x and u are reversed (interchange of the x and u columns) and a method of direct interpolation is used that does not presume equal intervals (perhaps Lagrange's formula or a divided-difference formula). Here, however, even if u can be well approximated by a low-degree polynomial in x, it does not necessarily follow that x can be well approximated by a polynomial in u of comparable degree. Thus the fact that a table has been constructed to permit direct polynomial interpolation should not lead to the assumption, without further investigation, that the reversed table will have the same property.

Reversion of Formulas.—When polynomial interpolation is justifiable for a table that gives u as a function of x, with x at a constant interval, but this table is not known to be dependable when reversed, it may be preferable to start with a formula that expresses u approximately as a polynomial in x and to invert the formula approximately by either numerical or analytical methods.

For example, if fourth differences can be ignored in Everett's formula (4), the result can be transposed as

$$s \approx \{(u_s - u_0) + \tfrac{1}{6} s(1 - s)[(2 - s)\delta^2 u_0 + (1 + s)\delta^2 u_1]\} \div (u_1 - u_0) \quad (7)$$

Here it is supposed that u_s is given and s is to be determined. Although (7) defines s explicitly only if $\delta^2 u_0$ and $\delta^2 u_1$ are negligible, a first approximation to s can be made by ignoring these differences in (7), after which a second approximation can be obtained by substituting this result for s in the right-hand member. This iterative process can be continued if necessary and usually will converge to the appropriate solution of (7), after which the desired approximation is given by $x_s = x_0 + sh$.

To illustrate this process, assume the data of Table III and seek x where $\log x = .4350000$. With $x_0 = 2.72$ and $h = .01$, formula (7) then gives $s \approx \{.0004311 - \frac{1}{6}s(1 - s)[.0000059(2 - s) + .0000057(1 + s)]\} \div (.0015937) = .270503 - (.001830 + .000021s)s(1 - s)$. The result of substituting the first approximation $s^{(1)} = .270503$ into the right-hand member rounds to .270141 and the substitution of $s^{(2)} = .270141$ yields the same result, to six places. Since the difference $u_1 - u_0$, which is the denominator in (7), is known here only to five significant figures (two digits being lost in the subtraction), the sixth digit in $s^{(2)}$ certainly is not reliable. The rounded final approximation $x_s = x_0 + sh \approx 2.7227014$ differs from the rounded true value by one unit in the last place. (F. B. Hi.)

INTERRACIAL RELATIONS. The great importance that has generally been attached to ideas of race, racial identity and racial differences in mentality and culture has in recent times played a major role in determining the relations between the peoples and nations of the world. A striking feature of these ideas is the fact that they have usually been based on a false conception of the meaning of race and on erroneous assumptions regarding its implications. Jacques Barzun, for example, entitled his book on this subject *Race: a Study in Modern Superstition*. Ashley Montagu speaks of *Man's Most Dangerous Myth: the Fallacy of Race*. Gunnar Myrdal, in *An American Dilemma*, expresses the opinion that in no other field is there so wide a gap between popular impressions and the conclusions reached by biological and social scientists. Race, in many of its aspects, exists only "in the minds of men."

The Problem of Definition.—The very term race is difficult to define. There is agreement to the effect that it is correctly applied to a subdivision of mankind which is distinguished by the possession of common characteristics, usually physical in their nature, determined by genetic or hereditary factors. Popularly, it has been confused with nation, although it is obvious that every modern nation is a mixture of inherited physical types; there is no British or Italian or German race. As a matter of fact, there is more physical or racial similarity between northern Italians and southern Germans than between the latter and Germans living in Hanover or Prussia. Similarly, there has been confusion between race and language; there is no Latin or Semitic or Aryan (Indo-European) race, since these languages are spoken by people of widely varying physical type. It follows that many of the phenomena usually included within the field of race relations have nothing to do with race as scientifically defined but rather with race as popularly, and erroneously, understood.

Difficulties of application remain even when care is taken to use race in the manner proposed by scientists. The geneticist Leslie C. Dunn, for example, believes that the word may have a valid biological meaning if applied to a group of related intermarrying

individuals which differs from other groups in the relative commonness of certain hereditary traits. This leaves unresolved the questions of how large the group should be or which traits should be used for purposes of classification. G. Sergi, using head form as a criterion, proposes two races, the Eurasiatic or roundheaded, and the Eurafrican or longheaded; J. Deniker, relying upon a combination of features including head form, skin colour and others, concludes that there are 17 main races and 29 subraces. If the criterion of head form is preferred, this would unite in the same category the blondest Scandinavian and the darkest Negro if both are longheaded. If the more usual category of skin colour is used, differences in head form are ignored or at least relegated to the background. This means essentially that racial classification at the present stage of our knowledge is at least to some extent an arbitrary and subjective process. A group of experts consulted by the United Nations Educational, Scientific and Cultural organization (UNESCO) expressed the view that three major human divisions should be recognized, namely, the Mongoloid, Negroid and Caucasoid, and this is probably as satisfactory a classification as any now available, but it does not include all human groups, nor does it solve all the problems that have been raised. The reliance on blood properties, particularly the four blood types A, B, AB and O, has facilitated significant genetic research, but has not as yet produced a satisfactory racial classification.

In view of these complications, it has been suggested that the term race should not be applied to existing human populations but should be replaced by the term ethnic group, which may be characterized by a particular inherited physical type, or culture, or nationality, or any combination of these. In any case, the geneticists have made it clear that the inherited similarities among all the peoples of the world are much greater and far more common than the differences and that the distinctions that have been drawn among the so-called races of mankind are relatively unimportant.

Racialist Thinking.—This similarity among peoples has not prevented a number of influential writers, political leaders and people generally from regarding alleged racial differences as having paramount importance. It is difficult to establish definitely the origins of what has frequently been described as racialist thinking, but certainly one of the most influential of such thinkers was Comte Joseph Arthur de Gobineau (*q.v.*), who published his four-volume *Essay on the Inequality of Human Races* in the middle of the 19th century. He taught the superiority of the white race over all others, and among the whites, of the Aryans as having reached the heights of civilization. This group was in fact considered to be responsible for civilization wherever it developed. The Teutons were taken to be the purest modern representatives of the Aryans, although Gobineau admitted that really "pure races" could no longer be found. As a matter of fact, he did not unequivocally favour such purity, since it was often at the point of contact and mixture between races that, in his opinion, civilization had a better chance to develop. This last point was conveniently neglected by many of his followers who, in the Gobineau societies which sprang up in Germany and elsewhere, not only glorified the Aryans and the Teutons but also insisted on keeping them "pure."

Gobineau's most important follower was H. S. Chamberlain (*q.v.*), who published *The Foundations of the 19th Century* in German in 1899. An Englishman by birth, he spent most of his life in Germany, where he was active in the Gobineau society, and was so popular with the ruling class that he became known as the kaiser's anthropologist. He, too, insisted on the superiority of the Teutons, whom he characterized physically as being for the most part tall, fair and dolichocephalic (longheaded), that is to say, corresponding to the Nordic type. He regarded the Jews as alien in spirit to the favoured Teutons, although he admitted the difficulty of distinguishing Jews from Germans on the basis of physical characteristics alone.

Although there were many other writers who developed the racialist position, such as Ludwig Woltmann and H. F. K. Günther in Germany, and Lothrop Stoddard and Madison Grant in the United States, Gobineau and Chamberlain may be regarded as the intellectual forerunners of the racial theories of the German Nazis. Hitler himself acknowledged his indebtedness to these theorists, particularly to Chamberlain, for giving him the "scientific" basis for this aspect of his political philosophy. There were, of course, inner contradictions in the racialist approach—the fact that so many Germans did not look like Nordics and so many Jews did, the alliance with the Japanese who had consequently to be exempted from the racial restrictions of the third *Reich*, the difficulty of giving any clear meaning to the concepts of German "blood" or "soul"—so that facts had to be replaced by mysticism. In spite of these and other deficiencies, racialism was used as a technique which helped to unify the Germans by identifying the "enemy," gave the people a strong sense of ego enhancement and self-confidence, justified economic exploitation and slave labour, obtained support for the war and convinced the Germans that they never could be defeated. Racialism thus functioned as one of the most effective techniques of Nazi propaganda for achieving and maintaining power over the German people.

Although colonialism cannot be compared with Naziism in terms of the violence and virulence of the human destruction it involved, it also found in racialism a helpful rationalization for conquest and expansion. When the Spaniards first came to America, several of their apologists, particularly Francisco de Quevedo and Juan Ginés de Sepúlveda, supplied them with the proper excuses for taking the land away from the Indians and for treating them with complete lack of consideration. They developed the theory that the Indians had an entirely different origin from that of the Spaniards, that they were not human in the same sense and that there was therefore no need to accord to them the same treatment as to one's fellow human beings. The familiar refrain of the "white man's burden," which was mainly of British manufacture and which found its literary expression in the writings of Thomas Carlyle, James A. Froude, Charles Kingsley and most strongly and clearly in those of Rudyard Kipling, made of imperialism a noble activity destined to bring civilization to the benighted members of other "races." What the British stood to gain as a result was never mentioned. Similarly, the French justified the maintenance of their colonial empire on the basis of their *mission civilisatrice*, their duty to bring civilization to the backward peoples of the world.

In all of these colonizing empires, there were undoubtedly many individuals honestly convinced of the nobility of their motives and their enterprise; at the same time, the feelings of racial superiority which accompanied colonialism played an important part in developing resentments among the colonized which even the recent trend toward emancipation and independence has not always made it possible to overcome. There has even developed in some parts of the world a sort of racialism in reverse, a degree of hostility of coloured peoples against whites as whites, which has caused considerable worry to the responsible leaders of all the groups concerned.

It remains true that in general, although with certain striking exceptions, the trend has been away from racialism. The rapid emergence of new nations, many of them former colonies, has meant that many more nations composed of "coloured peoples" have an independent voice in international affairs that commands a respectful hearing even from previous colonizers. The latter have, for their part, shown an evident willingness to grant such independence on an increasing scale. The recognition that the treatment of ethnic minorities within a country may have important implications for international relations has focused attention upon the need to improve intergroup relations in general. The work of scientists like Franz Boas in anthropology and Gunnar Myrdal and others in the social sciences has helped to destroy much of the mythological thinking associated with race. The trend has been reversed in the Republic of South Africa, where separation of ethnic groups has increased in recent years. In the United States, on the other hand, the movement has been gradually and progressively in the direction of providing greater equality of opportunity for all ethnic groups. The most dramatic expression of this tendency was furnished by the unanimous decision of the U.S. supreme court on May 17, 1954, based in part on social-science research, that the enforced segregation of Negro school children in certain states and localities was contrary to the principles of the U.S. constitution. (*See* NEGRO, AMERICAN.)

Studies of Racial Attitudes.—Although considerable progress has been made, a great deal of intergroup hostility remains, and much scientific effort has been expended in the attempt to understand its nature and its origin. One view has held that prejudice is inborn and inevitable; the philosopher Josiah Royce, for example, spoke of a "natural antipathy" against those who are different from ourselves. The fact that such antipathy is not found in young children, and the further fact that it does not occur in all individuals or even in all groups, throw considerable doubt upon this variety of explanation. There is, for example, much less prejudice against Negroes in Brazil than in South Africa or certain areas in the United States; there is more prejudice against Orientals in California and British Columbia than in Hawaii. Such variations are difficult if not impossible to reconcile with the theory that antipathy is natural and inevitable.

A variant of this theory is found in the writings of certain psychoanalysts who speak of a native aggressiveness or "death instinct" which may take the form of hostility against other ethnic groups. Others have suggested that aggressive tendencies can be explained as a consequence of the experiences of the individual, particularly the extent of his frustrations; the greater the frustration, other things being equal, the greater the tendency to aggressive action. Since, however, aggression may take many forms and may be directed against many different objects, this explanation does not carry us very far. The frustrated Brazilian does not look for a Negro scapegoat. There must be at least one additional factor; namely, that the individual learns what forms of aggression are permitted in his society, and against whom it may be expressed.

This learning process occurs in a variety of ways, and is facilitated from a number of different directions. In the home and in the school, the growing child learns, sometimes explicitly, sometimes indirectly, that others are "not like us," that they are not "our kind." The mass media often aid the process by developing or disseminating stereotypes of the pugnacious Irishman, the mercenary Jew, the lazy Negro, the dishonest Armenian—stereotypes that may frequently turn out to be untrue but which still affect our perceptions and our treatment of others. Institutions in the culture, sanctioned by law or by custom, which involve segregation, untouchability, occupational or recreational restrictions, may all contribute to feelings of ethnic or racial cleavage. A circular relation is established in which prejudice leads to discrimination, which in turn functions as an environmental support or stimulus for increased prejudice.

It is widely believed that our actual experience with members of other ethnic groups determines our attitudes toward them. This is undoubtedly true in many cases, but by no means always. Research has shown that there may be hostility or "social distance" among American students toward Turks, or among Guatemalans toward Jews, without any previous contact whatsoever. One investigator was able to demonstrate the existence of considerable rejection of even imaginary groups such as the Danerians, Pirenians and Wallonians, with whom there could hardly have been any unpleasant personal experience. This not only demonstrates the frequent irrationality of ethnic attitudes but also throws doubt on a theory described by the psychologist Gordon W. Allport as that of the "well deserved reputation"; namely, that if we dislike a particular group, they must certainly deserve our dislike. It seems more likely, as Eugene Hartley has suggested, that our attitudes toward other ethnic groups are not determined by contact with them but by contact with the attitudes that prevail in our community.

The question as to why such attitudes develop in the first place is not easy to answer, although at least a partial explanation can be found in the practical advantages that prejudice seems to confer on the dominant majority. The economic gain has been illustrated in the earlier reference to colonial expansion, in which a theory of racial superiority helped to rationalize and justify the expropriation of the property of others. This mechanism is easily discernible in the tendency to keep a minority "in its place," which essentially means to prevent it from competing with the dominant majority on equal terms. A second gain is represented by the practice of finding a scapegoat whom one can hold responsible for our ills, thus relieving ourselves of the obligation to blame ourselves for our shortcomings; the Jews served as such a scapegoat in Nazi Germany. A third gain, also illustrated by the Nazis, is in the feeling of superior status, of ego enhancement. A fourth may be described as a sex gain, which occurs when men of the dominant group have access to the women of the weaker but resist violently any effort by the men of the weaker group to obtain reciprocal privileges. The psychologist John Dollard believes that this was an important factor in maintaining the caste situation in the southern United States. This particular gain has evidently been renounced in South Africa, where all sexual contact between the races is strictly forbidden.

It should be added that prejudice and discrimination also involve significant losses. The sociologist Arnold Rose mentions, among others, the economic waste resulting from the failure to make adequate use of available manpower, the aggravation of social problems such as crime and delinquency, the harmful effect on international relations with the coloured peoples of the world, the creation of fears and anxieties and disrespect for the law. These are undoubtedly real losses, but they appear to be less obvious than the gains, which therefore are more likely to make themselves felt.

The gain in feelings of superior status and self-enhancement is related to a large amount of significant research on the part played by personality in the development of prejudice. Attention has been focused on the "authoritarian personality," characterized by generalized ethnocentrism but also by excessive conformity, rigidity, concern with status, a tendency to see the world as harsh and unfriendly and an inclination to favour strong punishment of deviants and offenders. This is only a partial list of traits found in prejudiced persons, who apparently "need" to feel superior to many out-groups and who dislike Jews and Negroes and Japanese and foreigners generally. The emphasis on the relation between prejudice and personality has added an important dimension to the understanding of intergroup relations, but it cannot be regarded as telling the whole story. Residents of South Carolina appear to be no more "authoritarian" than New Yorkers, but they usually have very different attitudes toward Negroes.

There is more than one dimension to prejudice. It may satisfy a number of different motives; it may be acquired in a variety of ways. An understanding of its many aspects, and of the manner in which they influence one another, has gradually replaced the attempts to explain the phenomena of race relations in terms of any one, single cause.

Similarly, programs designed to improve intergroup relations have become increasingly versatile instead of relying on any one method or technique. The debate as to whether one must first reduce prejudice before embarking on legislation to combat discrimination, or whether the approach should be the other way round, has yielded to the conviction that both procedures should be followed simultaneously. As a result, many nations have developed a program of education and information, including the revision of their school textbooks, in order to improve attitudes toward other ethnic groups, at the same time strengthening the laws that make racial discrimination a punishable offense. At the international level, UNESCO has directed its efforts toward giving wide dissemination to scientific facts concerning race; on the other hand, the United Nations has sought to give human rights the sanction of a universal declaration leading to a universal covenant.

The fact that progress has been made cannot obscure the resistances that remain to be overcome. The birth of the new nation-states in Africa and Asia has frequently been accompanied by difficulties of racial adjustment. The international political situation has, on the other hand, paradoxically had a favourable effect on race relations because of the desire on the part of all the great powers to win the friendship of these new nations. There have been other favourable factors also, including a changed climate of public opinion, as well as a general desire to counteract the impressions and heal the wounds that resulted from colonialism and imperialism. There is still a long way to go before race is universally recognized for the myth it really is, but the movement is in that direction.

See SEGREGATION, RACIAL; *see* also references under "Interracial Relations" in the Index.

INTERSTATE COMMERCE, a term widely used in the United States to denote commerce that crosses state boundaries or involves more than one state; it is distinguished from intrastate commerce that does not involve more than one state. Such a simple definition gives no hint of the complicated legal controversies through which the precise meaning of the term has been spelled out by the courts in more than 170 years under the federal constitution. The general trend in the 20th century has been toward including more and more activities under the heading of interstate commerce, and hence under control by the federal government. Few subjects in U.S. constitutional history have produced a greater harvest of judicial opinion and professional commentary.

Background.—During the 1780s, when the central government of the United States was based on the Articles of Confederation, the young nation went through the trials of its "critical period." One of the chief defects of the government under the articles was the absence of any central control over commerce with foreign nations and among the different states. The separate states, particularly those with large shipping and commercial interests, made their own regulations with little regard for the welfare of the country as a whole. It soon became clear that a new constitution creating a stronger central government was an absolute necessity. The new constitution that replaced the Articles of Confederation in 1789 gave the national congress power "To regulate Commerce with foreign Nations, and among the several States, and with the Indian Tribes." (art. I, sec. 8). In considering this grant of power, it must be recognized that the constitution created a federal system with powers divided between a central or federal government and the individual states that together make up the whole. The central government possesses only those powers delegated to it by the constitution. The remaining powers are "reserved to the States respectively, or to the people." (Amendment X.) If a specific act of congress comes within one of the powers granted to congress it is not only valid but is also the "supreme Law of the land . . . any Thing in the Constitution or Laws of any State to the Contrary notwithstanding." (Art. VI.) If it is not within such a grant it is invalid or, in the language of the U.S. courts, "unconstitutional." Under the established polity of the United States the duty of determining whether an act of congress or of any individual state is valid or invalid rests with the courts and ultimately with the supreme court of the United States. It is therefore in the reported opinions of that tribunal that one must turn to ascertain the nature and effect of the power of congress to regulate interstate commerce.

Federal and State Powers.—The problem divides into two distinct but related issues: (1) the extent of the power granted to congress; and (2) the effect of such grant on the powers of the several states. It would be simple if these issues could be determined by pure syllogistic logic—by defining what it is that constitutes power to regulate commerce among the several states, and by ascertaining whether the particular law in question comes within that definition. In some notable instances, such as *Gibbons* v. *Ogden* (9 Wheat. 1 [1824]) this method has been used. Customarily, however, the court has not confined itself within such mechanistic limits. The power it possesses of determining the validity or nonvalidity of the laws of the federal and state governments necessarily makes it an arbiter between these two elements of the federal system. In such role it recognizes the responsibility of assuring the central government of power sufficient to preserve and advance the welfare of the nation as a whole, and also of according to the individual states the authority necessary to conserve their own legitimate local interests. Such an approach does not lead to an orderly and permanent pattern of law. The course of decisions shifts and varies according to the nature of the issues in individual cases, according to the prevailing opinions of the proper role of the federal and state governments in the affairs of the people, and according to the views of the individual justices on these great underlying issues.

The Commerce Clause.—Consideration of the basic elements in the commerce clause is necessary. "Commerce" includes transportation—the carriage of persons and commodities—and also trade—the buying and selling of goods. Commerce is interstate when the transportation crosses state lines and when the trade contemplates the movement of the subject matter across such lines. The commerce is interstate not only at the moment the state lines are crossed, but it has that quality from the time the transaction is initiated until it reaches its final conclusion, including all the elements thereof, even though within the confines of a single state. The power to regulate is simply the power "to prescribe the rule by which commerce is to be governed." In spite of possible implications, "commerce among the several states" does not require that financial considerations enter into the transaction. A man who transported from California into Nevada a woman there to become his mistress was held engaged in interstate commerce, and subject to the law of congress imposing criminal penalties on anyone transporting a woman across state lines for an "immoral purpose." Interstate commerce is, of course, not confined to the types of transportation and trade that were in existence when the constitution was adopted, but includes transportation by railroad, automobile and airplane, and the transmission of intelligence by telegraph, telephone, radio and television. Also covered by the clause in question are the news-gathering activities of the press services, and education by correspondence schools. Although it was at one time held that the interstate business of insuring against risk was not interstate commerce under the constitution, the decision was later repudiated.

POWERS OF CONGRESS

General Concepts.—Since the constitution confers no general lawmaking power upon congress, it is upon the interstate commerce clause, coupled with the grant of power to make such laws as are "necessary and proper" to carry out a specifically granted power, that the very considerable body of federal regulatory law principally depends. When such commerce is found to exist, then the power of congress over the transactions involved is as positive and complete as that of any state over transactions taking place entirely within its borders. When, in the 1880s, the stock raisers and farmers of the western plains were oppressed by the exorbitant rates and discriminatory practices of the railroads that moved their products to market, congress passed the Interstate Commerce act of 1887. This law required that all interstate rates be just and reasonable, and that no preferences be allowed to any person, place or type of business; it also created an Interstate Commerce commission to administer its provisions. Similar regulations were later enacted for interstate motor carriers, air transport, transmission of electric energy, and for telegraph and telephone lines, radio and television. In 1890 the Sherman Antitrust act

made illegal all combinations in restraint of interstate transportation and trade, and all attempts at its monopolization. In 1914 federal control was further implemented by the Clayton act and the Federal Trade Commission act.

With perhaps some strain of interpretation the power to regulate interstate commerce comprehends the power to prohibit it. The U.S. supreme court has said: "Congress can certainly regulate interstate commerce to the extent of forbidding and punishing the use of such commerce as an agency to promote immorality, dishonesty or the spread of any evil or harm to the people of other states from the state of origin." (*Brooks* v. *United States*, 267 U.S. 432 [1925], sustaining a federal statute making it a crime to transport a stolen automobile in interstate commerce.) Of a similar character are statutes making it a federal crime to transport in interstate commerce lottery tickets, women for immoral purposes and intoxicating liquor into a state whose laws prohibit its use. The far-reaching federal Food, Drug and Cosmetic act (1938) and the Meat Inspection act (1906) rest on a similar foundation. And in order to enforce the prohibition the federal government may proceed against those handling the product whether before the traffic has begun or after it has been completed.

In the case of *Hammer* v. *Dagenhart* (247 U.S. 251 [1918]) a closely divided court held that it was not within the power of congress to prohibit the shipment in interstate commerce of the products of child labour. The cases that had supported similar enactments were distinguished on the ground that in them the use of interstate commerce was necessary to accomplish the evil purpose, whereas in the child labour case the goods themselves were proper and harmless. The purpose of the statute, the court declared, was to control manufacture in the individual states, a matter reserved to the several states and not granted to congress. The decision did not, however, stand the test of time, and was later overruled. (*United States* v. *Darby*, 312 U.S. 100 [1941] upholding the Fair Labor Standards act.)

The national power over interstate commerce is not confined to measures necessary to prevent its employment in harmful ways, but supports as well federal action preserving and protecting it against such acts as would impede, injure or destroy it. In an early case the court held it within congressional power to provide punishment for theft from vessels wrecked on the high seas. Upon this concept rests the power of the courts under the antitrust acts to enjoin combinations designed to prevent interstate transportation or trade. The commerce power thus extends not only to interstate commerce itself but to all other transactions which "affect" it, even though not interstate in scope nor even—as in the cited cases—"commerce" at all. In the case of *United States* v. *Wrightwood Dairy Co.* (315 U.S. 110 [1942]) the supreme court said:

> The commerce power is not confined in its exercise to the regulation of commerce among the states. It extends to those activities intrastate which so affect interstate commerce, or the exertion of the power of congress over it, as to make regulation of them appropriate means to the attainment of a legitimate end, the effective execution of the granted power to regulate interstate commerce. . . .

Under this concept the power that congress may wish to exercise under the commerce clause appears almost limitless.

Transportation.—Congressional regulation of the nation's transportation systems is almost complete; it extends far beyond the bare act of interstate transport and touches many matters that normally would be reserved to the authority of the individual states. In numerous instances it is required that a federal licence be obtained before an interstate commerce enterprise is undertaken. In 1870 the supreme court sustained a statute requiring inspection and licensing of vessels operating on inland waters, where the vessel in question carried goods in interstate commerce, even though it operated solely within the confines of a single state. By the middle of the 20th century the requirement of a federal licence in the crowded fields of interstate motor and air transport and in radio and television transmission had become a matter of transcendent importance.

The purpose of the Interstate Commerce act was to regulate interstate rates of the railroads to the end that they be just, reasonable and without discrimination. This power was later extended to motor-vehicle and airplane rates. The appropriate regulatory body is also empowered to require the establishment of joint rates for traffic moving over several lines, and to provide for the division of the receipts between the participating carriers. Whenever there is a single continuous journey between different states, the rate-fixing power of the United States extends to each portion thereof, even though one portion may be conducted by a separate carrier and be confined within the limits of a single state. The federal rate power is not only regulatory, but may also be employed to maintain an adequate national transportation system and to promote the general economic welfare of the nation. The federal power may extend even to the fixing of purely intrastate rates. When two cities compete for the trade of a particular area, one being located across a state line and shipping goods in interstate commerce, and the other being located within the same state shipping in intrastate commerce under lower rates, the commission may require the railroads involved to increase the intrastate rates to the level of the interstate rates to prevent discrimination. The power was subsequently extended to permit the commission to increase intrastate rates when it was shown that they did not provide a fair share of the expenses incurred in operating the railroad as a whole.

Under the provisions of the Interstate Commerce act that prohibit unreasonable preferences to or discriminations against any particular person, place or type of business the supreme court has held contrary to federal right the imposition by carriers, as applied to interstate travelers, of racial segregation, not only in transportation itself, but also in sleeping-car and dining-car service, and in the accommodations furnished in terminals and waiting rooms.

In order to protect persons (including railroad employees) and property transported in interstate commerce, certain specific requirements as to equipment are imposed on the railroads. Moreover, so intermingled is the interstate and intrastate traffic of the roads that failure of the railroad to comply with terms of the statute even as to cars not then employed in interstate traffic subjects it to the penalties of the statute.

Adequate regulation of interstate transportation can hardly be achieved without control over the corporations that own and manage the interstate transit systems. In the historic case of *Northern Securities Co.* v. *U.S.* (193 U.S. 197 [1904]) the court, acting under the Sherman Antitrust act, sustained an injunction against acquisition by the defendant of the stock of the competing Great Northern and Northern Pacific railroads. It has since become a well-established principle that the Interstate Commerce commission has power to control the merger and consolidation of interstate railroads and of airlines. To assist it in carrying out its functions the commission may require the carriers under its supervision to maintain a uniform system of accounts. To prevent monopoly and to secure efficient management in the gas and electric industry, congress in 1935 enacted the Public Utility Holding Company act, providing for the breakup and reconstitution of the sprawling holding companies in that industry.

Because interstate transportation can be conducted only by the employment of human labour the law governing labour relations falls within the regulatory power of congress. In the first *Employers' Liability* cases (207 U.S. 463 [1908]), however, an act of congress modifying certain of the common-law rules governing the liability of employers for personal injuries to employees was held unconstitutional, since it applied to all employees and not merely to those engaged in interstate commerce. A later act, which applied only when the injured employee was at the time engaged in interstate commerce, was sustained. (Second *Employers' Liability* cases, 223 U.S. 1 [1912]). Following these cases there inevitably arose a multitude of decisions on the difficult question as to which acts of an employee could be deemed to involve interstate commerce. The outcome was that the law covers any employee any part of whose duties are in furtherance of interstate commerce, or closely and substantially affect it.

When disputes between a railroad and its employees lead to work stoppages or strikes, interstate traffic is obviously stopped. To prevent such occurrences, congress in 1934 enacted the Rail-

way Labor act that required employers and employees to settle their differences through conferences, agreements, mediation and finally by voluntary submission to arbitration. Specific sections of the act forbade the interference by either party with the choice of representatives by the other, and conferred on the employees the right, without interference by the employer, of joining unions of their own choice. These latter provisions have been upheld as reasonable measures of securing settlements of disputes and preventing interruption of commerce.

As natural highways for interstate and foreign traffic, the navigable waters of the United States have from the very beginning been recognized as being under the jurisdiction of congress. Congress may either prohibit or permit the erection of piers and bridges on and over navigable waters. Congress has adapted this power over navigable waters to many different activities. The agricultural and industrial development of the Tennessee valley rests upon the power to improve navigation by building dams on the Tennessee river, and, as ancillary to that purpose, the disposal of the power thereby developed. *United States* v. *Appalachian Electric Power Co.* (311 U.S. 377 [1941]) sustained the authority of the Federal Power commission to grant licences for dams on navigable rivers, though the dams were useful only for power purposes, and to impose conditions on such licences, though unrelated to navigation. The power of congress over navigable waters is plenary and the development of navigation thereon but a part. In 1941 the supreme court sustained the construction of a dam—under an act of congress—on an unnavigable portion of the Red river, a tributary of the Mississippi, since the dam would help to prevent floods on the Mississippi, which was, of course, navigable.

Trade.—In the 20th century the sanction of the supreme court has been accorded federal regulation of matters that in earlier times would have been considered local and solely for state control. These holdings were foreshadowed as early as 1905 when the court sustained an injunction under the Antitrust act against a combination of the meat packers to control prices paid for cattle in the stockyards. Even though the purchases took place locally, the transactions involved were in what was described as the "current of commerce," and the court held that strict legal rules should not deprive the government of control over matters that so closely affected interstate commerce. (*Swift and Co.* v. *United States,* 196 U.S. 375 [1905].) Later cases relied on this decision to sustain the constitutionality of federal regulation of the stockyards, of trading in grain futures and of the inspection and grading of tobacco in the tobacco markets. The activities in question were not, taken separately, interstate, but since they affected prices charged in interstate trade, they came under the federal power. The Fair Labor Standards act of 1938 not only prohibited the shipment in interstate commerce of goods produced contrary to the standards of the act but directly prohibited the payment to employees engaged in the "production of goods for interstate commerce" wages lower than those prescribed by the act, or the exaction of longer working hours. The prohibitions were sustained as means of preventing shipment of such goods; the court held that production of goods in one state under substandard labour conditions would through the force of competition prejudice industry in those states where proper standards were maintained, and thus "affect" interstate commerce. The National Labor Relations act of 1935 extended to employees in commerce and industry generally the same rights of organization and collective bargaining as are accorded to employees in transportation, as previously mentioned. In the case of the *National Labor Relations Board* v. *Jones & Laughlin Steel Corporation* (301 U.S. 1 [1937]) the supreme court upheld the act as applied to a manufacturer of steel. The opinion covered familiar ground. Labour disputes lead to strikes, which stop the flow of goods in interstate commerce. Recognition of the right of employees to form unions and to bargain collectively is a means of preventing strikes and is thus within the federal power. The word "affect" has been liberally interpreted. *Consolidated Edison Co.* v. *National Labor Relations Board* (305 U.S. 197 [1938]) held the act applicable to the electric utility serving metropolitan New York city. Although the utility was not itself in interstate commerce, part of its sales were to railroads and other enterprises in interstate commerce, and thus the act was held to be applicable to the utility.

Since the 1920s congress has struggled with the problem of inadequate prices and overproduction in agriculture. The Agricultural Marketing Agreement act of 1937 authorized the secretary of agriculture to fix minimum prices for purchase of specified agricultural commodities "in the current of interstate commerce or which directly burdens, obstructs or affects interstate commerce." In *United States* v. *Rock Royal Co-operative, Inc.* (307 U.S. 533 [1939]) the supreme court upheld under this act an order fixing minimum prices for fluid milk in the metropolitan New York area paid farmers in sales to local plants. Although these sales were by themselves intrastate transactions, the ultimate destination of the product was interstate commerce. Where the interstate and intrastate transactions are inextricably mingled the federal power extends over the whole. *United States* v. *Wrightwood Dairy Co.* (315 U.S. 110 [1942]), involving the same act, went farther and sustained an order of the secretary of agriculture fixing prices in the Chicago market, though the dairy in question purchased only from Illinois producers and distributed only to Illinois consumers. The secretary could not adequately regulate the entire market, the court ruled, if intrastate operators sold at lower rates than did the interstate operators. Federal power moved even more deeply into what appeared to be local affairs in the Agricultural Adjustment act of 1938, which attacked the problem of agricultural overproduction. Under the terms of the act there was allotted to one Filburn, a small Ohio farmer, 11.1 ac. on which he could plant wheat. Filburn planted 20 ac. Although he sold no wheat, but used it solely for his own consumption, the supreme court in the case of *Wickard* v. *Filburn* (317 U.S. 111 [1942]) held him subject to the penalties of the act. Filburn's consumption of wheat that he had grown himself relieved him of the necessity of buying wheat in interstate commerce; interstate commerce was affected; and thus, the court held, the power of the federal government was applicable. After this group of decisions, *Schechter Poultry Corporation* v. *United States* (295 U.S. 495 [1935]), holding the attempt under the National Industrial Recovery act to control the live poultry market in New York city, and *Carter* v. *Carter Coal Co.* (298 U.S. 238 [1936]), holding invalid the regulation of hours and wages in bituminous coal mines, were no longer authoritative.

POWERS OF THE STATES

Regulatory.—In the landmark case of *Gibbons* v. *Ogden,* cited above, Chief Justice John Marshall raised, but did not decide, the question whether the grant to congress of power to regulate commerce among the states did not necessarily exclude the states from exercise of like power. The later case of *Cooley* v. *Board of Wardens* (12 Howard, 299 [1851]) decided the issue in a manner that was thereafter uniformly followed. Some subjects of the power are national in their nature and thus demand a single uniform system of regulation. As to these the power of congress is exclusive. With other subjects, conditions differ from state to state, and as to these, diversity rather than uniformity is desirable; here the states, in absence of a federal statute on the matter, have the power of regulation. On this ground the court sustained the Pennsylvania law requiring ships arriving from or bound to a foreign port to engage a local pilot while in the port of Philadelphia. The test permits no easy or automatic application, since, in essence, it calls for striking a balance between national and state interests.

In one respect, however, the rule was at first positive. Engagement in interstate commerce is a federal and not a local right, and statutes requiring state licences to engage therein are invalid. The rule has its usual application in respect to corporations. Although in general a state may prohibit a corporation that is not incorporated nor licensed by it from doing business within its borders, the prohibition cannot apply when the corporation is engaged in interstate commerce. The main rule does not apply when the corporation involved, though engaged only in interstate commerce, has its principal place of business in the state nor, apparently, when the requirement of permission is a reasonable method of protecting the people of the state from the practices of possible dis-

honest and irresponsible companies. Apart from the incorporation phase of the problem, the former rule was that a state, even to protect its people from fraud or imposition, could not require a state licence nor impose conditions on interstate transactions such as buying grain for interstate shipment. Subsequent cases, however, sustained such enactments on the ground that the activity involved was essentially local.

Clearly, as contrary to the *raison d'être* of the commerce clause, a state may not insulate any portion of its own intrastate commerce from interstate competition. For example, a statute that forbade natural gas producers in one state to pipe their product into adjoining states, until the needs of local consumers had been satisfied, was held invalid.

The regulation of rates for transportation from, to and through several states is obviously a matter requiring single national control. *Wabash, St. Louis and Pacific Railroad Company* v. *Illinois* (118 U.S. 557 [1886]) held such an attempt by the state of Illinois to be invalid and was the occasion for the enactment of the federal Interstate Commerce act in 1887. Since that time there has been considerable litigation on the question whether the particular rates fixed involve interstate or intrastate transactions. State regulations of interstate commerce designed to protect the personal safety of citizens, or to secure adequate service, have been sustained. The courts have also upheld state laws requiring railroads at highway crossings to check the speed of their trains, maintain watchmen or eliminate grade crossings. In all these respects, however, if the regulation in question is found unreasonably to hamper or burden the interstate commerce function of the railroad it becomes invalid.

Where interstate transportation is over public highways, the propriety of regulation by the several states is more apparent. The highways are subject to wear and tear, and there are hazards to life and limb of other users. In the earlier days of automobile traffic the supreme court sustained state laws requiring a licence for the use of its highways, and imposing fees for its issuance to compensate the state for the use of its roads and the cost of the regulation. Where, however, state permission is required, not for these reasons, but in order to prevent undue competition—then, as in other cases, the requirement by a state of a permit to engage in interstate commerce is invalid. The several states may, for safety and other reasons, regulate the weight and equipment of vehicles traveling their highways but when shown that the requirements are unreasonable the rules in question become invalid.

Of a somewhat different character from the laws just discussed are those statutes prohibiting the entry into a state of persons or goods likely to spread disease. Quarantine laws, except where found unnecessarily restrictive, are upheld because in these cases the local interest outweighs the national. In the case of *Edwards* v. *California* (314 U.S. 160 [1941]), however, the court invalidated a statute punishing transportation of indigent persons into the state because the constitutional right of U.S. citizens to move from state to state was involved. When, however, the harmful character of the inhibited goods is not universally recognized, then the law is not so clear. Long before adoption of the 18th or prohibition amendment in 1919, laws of certain "dry" states prohibiting the shipment of intoxicants into the state were held invalid. Intoxicating liquor was a recognized article of trade, and the court ruled that a single state could not prevent the shipment of liquor into its borders. In the 1940s, after repeal of the prohibition amendment, statutes regulating the transportation of liquor through a state were upheld. Laws requiring that before certain commodities may be transported into a state they must be inspected to determine whether they endanger the public safety, are instruments of possible fraud or are otherwise detrimental to the common welfare, are universally sustained.

When congress has legislated on a particular subject the rule of federal supremacy makes state law to the contrary invalid. When no direct conflict exists, but both federal and state law cover the same general subject matter, a different problem arises. One line of cases holds that legislation by congress in a particular field is an implied prohibition of state legislation in the same field. For example, a federal act requiring in considerable detail certain equipment on locomotives was held to preclude the states from making additional requirements. A second line of cases, however, permits state authority to operate in the interstices not covered in the specific provisions of a federal law. The National Labor Relations act occupies a middle ground. In general, the states may regulate labour-management relations in areas over which the federal authority has not been extended. Thus it has been held that the states may, in spite of that act, prohibit mass picketing and forbid periodic unannounced work stoppages by employees. Where, however, the federal law does govern a specific segment of labour-management relations, particularly when it confers positive rights, then state regulation in that field must give way. For solving the problems presented in this paragraph, it would appear that canons of statutory construction and rules of logic may be outweighed by the relative importance of the national and state interests involved, and by the practical aspects of administering the various laws in question. Diversity of decision has been the result.

Taxation.—Taxes have been defined as the price one pays for the benefit of government, and since it is on the governments of the several states that those engaged in interstate commerce depend principally for the protection of their properties, activities and other interests, it follows that they must pay state taxes. Nevertheless, taxes "affect" such commerce, and accordingly the state taxing power is subject to the jurisdiction of the federal courts. Taxes may be levied on privileges and franchises; on gross receipts or net income; on sales of goods or on the privilege of using goods; and, of course, on property. Each of these modes of taxation has its own particular problems, but in each of them runs the necessity of striking a balance between protecting interstate commerce from undue burden and allowing the states sufficient sources for their tax revenues. The resulting fusion of law and policy has led to a great volume of litigation, and the drawing of many fine lines of distinction. One thing is clear, however. The states, in whatever manner they may exercise their power to tax, cannot favour their own internal commerce and discriminate against interstate commerce.

The conduct of interstate commerce is a right conferred by the U.S. constitution, and, as the states cannot require a licence for its exercise, neither can they levy a tax on it. For example, a city ordinance levying an annual tax of $225 on telegraph companies doing business in the city was held invalid when a part of such business was interstate. The imposition of a fee for soliciting the sale of goods by sample was likewise held to be void when the solicitor in question represented a merchant of another state. A state may not levy upon a corporation organized in another state a tax on the privilege of doing business in the corporate form in the state of the levy when such business consists solely of interstate commerce.

A state tax that involves neither interstate commerce nor a subject matter so connected therewith as to be deemed a part thereof is perfectly valid. There are numerous decisions, some upholding and some invalidating the tax, depending on how vitally interstate commerce is deemed to be affected by the levy. It sometimes happens that certain transactions, though held sufficiently related to interstate commerce to be regulated by congress, are nevertheless held subject to tax by the states. Where both interstate and intrastate commerce is conducted, state privilege taxes assessed on the latter business are sustained. *Western Union Telegraph Co.* v. *Kansas* (216 U.S. 1 [1910]) qualified this rule, however, holding that where the intrastate business was but a small fraction of the entire business transacted, a tax on such intrastate business based on a percentage of the corporation's entire capital, most of which was employed out of the state, was in effect a tax on the interstate business and on property located beyond the jurisdiction of the state, and hence invalid. This decision led to a large number of other supreme court cases. The final result seems to be that annual franchise taxes on foreign corporations engaging in both interstate and foreign commerce, when based on the entire capital and business of the corporation, are invalid; where based on the proportion that the capital employed or business conducted in the state bears to the whole, they are valid.

As noted above, automobile licence taxes, reasonable in amount,

apply to all vehicles, including those employed only in interstate commerce. They are regarded as compensation for the use of the state's highways, and it is immaterial whether the exaction be a flat sum, or be computed on some such basis as value, weight, carrying capacity, miles traveled or gross revenue. Also, it is not essential that the revenue obtained be applied directly to the building and maintenance of highways. If, however, under the state statute the exaction cannot be regarded as compensation for use of the highways, then it is an invalid tax on the privilege of engaging in interstate commerce.

Taxes on gross receipts from commerce are, because of their practical effect, held equivalent to taxes on the privilege of engaging in commerce, and are invalid when levied on gross receipts from interstate transactions. They may, however, be levied upon the proceeds from intrastate operations. The court is thus faced with the problem of drawing the line between transactions that are interstate and within the protection of the interstate commerce clause, and those that are local and not within such protection. In the former group are decisions holding invalid gross receipt taxes from transportation between points in a single state but through other states; radio broadcasting; sales of securities on stock exchanges by residents of other states; stevedoring on vessels in foreign and interstate commerce; and from services as agents for fruit growers selling their products in other states. On the other hand, taxes have been upheld on gross receipts from local sales, whether they be of goods destined for shipment to another state for processing by the seller, or whether from sales in the original packages in which the goods were shipped to the seller from another state.

In contrast to taxes on the gross receipts from interstate commerce, nondiscriminatory taxes on the net income from such commerce are upheld. In this case the impact of the tax is not so severe, and the tax, like taxes on the property employed in the commerce, is held "indirect," and not violative of the implied prohibitions of the interstate commerce clause.

Sales taxes, analytically considered, are levied on the privilege of buying and selling goods. Accordingly, where the transaction is interstate, no state tax can be levied on it. Such characterization is, however, sparingly conferred. A sale is not excluded from taxation merely because the seller acquired the subject matter through interstate commerce and is selling it in the original package nor because the buyer is purchasing the goods for transport into another state. A New York city tax on sales to New York residents was upheld even though the goods were shipped from another state, the seller was incorporated in and had its principal place of business in another state, and in such other state the contract of sale was finally effected. The taking of orders for the goods by the sellers' representatives with established businesses in New York, and the delivery there of the purchased goods gave to the sales sufficient local incidence to enable the city to levy the tax. No tax was, however, leviable in the state of the purchaser if the buyer submitted his order directly to the out-of-state seller, or, if to agents of the seller, such agents had no settled place of business in the buyer's state. To prevent escape from state sales taxes by such methods or through journeys to, and purchases in, neighbouring states that had no sales taxes, the sales-tax states resorted to so-called "use taxes." They imposed taxes equal in amount to the sales taxes for the use of property brought into the state on which no sales tax had been levied. Such taxes are valid. They are justifiable attempts to conserve the levying state's sales tax revenues; the property in question has passed out of interstate commerce and come to rest in the state; and from the combination of the sales and use taxes, equality of burden and not discrimination results.

State taxation of the property of the interstate carriers has always been upheld. The property receives state protection and the taxes thereon are the price paid for the protection. Such property has its own particular characteristics. Most of the individual items of the property—the rolling stock of the railroads, the vehicles of the truck and bus lines, the planes of the airlines—are constantly on the move throughout the entire system of the carrier and are in a single state only temporarily. Nevertheless, in each state there is constantly on hand a fairly constant average of such property. The individual items of property are integral parts in the entire system of the carrier and as such have a value that may be greater than the value of the items considered individually. The taxable value of the property of the carrier within a particular state then, is that proportion of the value of the entire property of the carrier devoted to commerce that the property in the taxing state bears to the total value. To determine this proportion several different factors have been utilized: track mileage, car mileage, gross receipts and net income. Taxes levied through such formulas are not taxes on the factors employed, but taxes on property, and if through them a fair approximation of the value of the property within the taxing state is obtained, they are valid. Where, however, the formulas employed result in a valuation greatly in excess of the true value of the property affected, then the tax is invalid. In *Northwest Airlines* v. *Minnesota* (322 U.S. 292 [1944]), the supreme court by a bare majority held that the state of Minnesota, where the company was incorporated and which was the main base of its operations, could tax all the planes of the corporation, even though a determinable fraction thereof was constantly in operation in other states. Continuing litigation resulted, the final conclusion being that the domiciliary state of the carrier may still assess all of its movable property devoted to such business, except as the taxpayer can prove that a determinable portion thereof has acquired a situs in another state or states, subjecting it to taxation therein. (*Central R. Co.* v. *Pennsylvania,* 370 U.S. 607 [1962]).

Property of the shippers while in interstate transit also has peculiar characteristics. It is customarily in the taxing state for but a few days, and the shipper has not, as the carrier has, a constant average of property in the state. Moreover, since the several states often provide different days on which the assessment of property is made, there is great possibility that property in transit might be subject to multiple taxation. The accepted rule, accordingly, has always been that property in transit in interstate commerce is not taxable by the several states. For this purpose interruptions in the actual movement of the goods, when due to the necessities of the interstate movement, as where property is stored awaiting transshipment to another carrier, do not take the property for tax purposes out of the interstate movement. *Champlain Realty Co.* v. *Town of Brattleboro* (260 U.S. 366 [1922]) held that logs being rafted from Vermont into New Hampshire, though detained for several weeks in the former state by conditions of the rivers, were still in interstate transit and not taxable by Vermont. The transit does not begin until the property in question is either started on its journey or delivered to a common carrier for such transport, and the transit comes to an end when the property is delivered to the custody of the consignee. The circumstance that it may be in the original package in which it was shipped is for this purpose immaterial. The so-called "original package" rule of *Brown* v. *Maryland* (12 Wheat. 419 [1827]), which frees from state taxation property of an importer from foreign countries while it is in the original package, does not apply to interstate commerce.

See CONSTITUTION AND CONSTITUTIONAL LAW: *United States;* FEDERAL TRADE COMMISSION; LABOUR LAW; *see* also references under "Interstate Commerce" in the Index.

INTERSTELLAR MATTER is material of exceedingly low density dispersed in the space between the stars in the form either of gas (detectable from its emission and absorption of light and radio waves, especially in certain spectral lines) or of "dust," which can be detected by its general absorption and reddening of starlight.

DARK MATTER IN THE MILKY WAY

Absorbing Clouds.—Inspection of the Milky Way with a small telescope (or in places with the naked eye) shows that the rich

star fields of which it consists are interrupted by dark patches, such as the Coalsack near the Southern Cross. These dark areas were examined around 1900 by Max Wolf and E. E. Barnard, who found them to be most abundant in Ophiuchus and Sagittarius, toward the centre of the Milky Way system. This fact, together with the appearance among them both of bright patches and of still darker globules, suggests that they are really dark clouds rather than starless "holes," which latter would have to be narrow tubes thousands of light-years in length converging on the solar system —an obvious absurdity. The absorptions, distances and thicknesses of these clouds have been determined by a method originated by Wolf and improved by later workers: the apparent distances of stars (found from their spectral types and apparent brightnesses) are determined both through a cloud and in a neighbouring field outside the cloud. The number of stars at a given distance is then plotted on a graph against this distance for the two cases; the two curves coincide up to the distance of the near side of the cloud and then diverge until, on the far side, they run parallel with a constant horizontal displacement from which the amount of light absorbed by the cloud can be calculated. The results are greatly complicated by the frequent presence of several clouds in one direction, but a typical cloud seems to be about 100 parsecs across (1 parsec = 3.26 light-years) and to diminish the light passing through it by nearly 1 magnitude (equivalent to a factor of 2.512).

A further effect, known as interstellar reddening, arises in the clouds because blue light is absorbed more strongly than red light; hence a given star appears redder through a cloud than when seen through clear space, just as the sun appears red when near the horizon. The colours of stars are measured by their colour index; *i.e.*, the difference between photographic or blue magnitude (measured in a wave length band centred near λ 4250 Å) and visual magnitude (centred near λ 5450 Å in the yellow-green region). The amount by which the colour index of a star exceeds the normal value for its spectral type is known as its colour excess. In most clouds studied, the ratio of total absorption in photographic magnitude to colour excess has nearly the same value, about 3.5, suggesting the presence of the same absorbing material in these various cases. This fact has been applied by W. Becker and by H. L. Johnson and W. W. Morgan in order to obtain the degree of interstellar absorption and reddening for star clusters by comparing the normal colour index with an additional colour index obtained from photometry in the ultraviolet region of the spectrum (λ 3600 Å).

General Absorption.—The possibility that the light of distant stars might be dimmed by absorption even where no dark clouds are actually visible was mentioned in 1720 by Edmund Halley, and discussed during the 19th century by H. W. M. Olbers, F. G. W. von Struve and others as a possible explanation of the fact that the number of stars per unit volume seems to diminish with distance in all directions. The alternative explanation is that we are near the galactic centre.

The 20th-century research on our galactic position has shown that we are close to the central plane of the galaxy, but a long way from the centre, so that the apparent distribution of stars in the Milky Way (though not at right angles to it) is indeed determined by absorption, although the amount of absorption varies greatly with direction and distance. Definite proofs of the presence of general absorption in the Milky Way have been provided by the invisibility of external galaxies in an irregular region roughly bounded by the circles of galactic latitude ± 20° ("zone of avoidance" studied in detail by E. P. Hubble and H. Shapley) and by R. J. Trumpler's extensive investigation in 1930 of galactic open clusters at distances between 600 and 2,200 parsecs.

By measuring the apparent brightnesses of cluster stars whose real brightnesses could be estimated from their spectra, Trumpler estimated the actual diameters of the clusters and showed that these must increase systematically with the distance of the clusters from us if the intervening space were assumed to be entirely transparent. This highly implausible effect is removed if one assumes an average absorption of about 1 photographic magnitude per 1,000 parsecs in the galactic plane.

RADCLIFFE OBSERVATORY (PRETORIA, U. OF S. AF.) PHOTOGRAPH, REPRODUCED BY COURTESY OF A. D. THACKERAY

M 16. A COMPLEX OF BRIGHT AND DARK INTERSTELLAR MATTER IN SERPENS, IN THE SOUTHERN MILKY WAY

A similar result was obtained by A. H. Joy (1939) and R. E. Wilson (1940) from a study of Cepheid variables whose absorptions and true distances were derived from the period–luminosity relation in conjunction with the theory of galactic rotation; but J. H. Oort, H. C. van de Hulst and D. W. N. Stibbs later suggested twice this value. If the absorption is neglected, large distances are greatly overestimated; for example, the distance of the galactic centre—estimated at 16,000 parsecs by Shapley in 1930—turns out to be only 8,200 parsecs when the obscuration is allowed for. W. Baade's photographs of external galaxies suggest that the absorbing clouds are mainly confined to galactic spiral arms.

Scattering Nebulae.—When observed with a spectroscope, certain bright nebulae show a continuous spectrum with dark lines, identical with that of a nearby star, unlike the emission spectra of gaseous nebulae near very hot stars. These bright nebulae are identical with the dark clouds mentioned above, which scatter incident starlight in all directions and thus appear bright when viewed sideways on. As in the case of the sunlit sky, but to a lesser degree, the scattered light is generally more blue than that of the illuminating star and shows a certain degree of polarization (*see* below). True absorption of starlight by obscuring clouds is probably absent, and the term "interstellar absorption" should strictly be interpreted as obscuration resulting from scattering by interstellar material.

Interstellar Polarization.—In 1949 W. A. Hiltner and J. S. Hall showed that the light of distant stars seen through obscuring matter often possesses an appreciable degree of polarization; *i.e.*, the electric vibration of the light is slightly (up to 8%) stronger in one plane than in the plane at right angles to it. The polarization is particularly strong toward Perseus, where we are probably looking along a spiral arm of the galaxy. In this direction, the strongest vibration is parallel to the galactic plane; this suggests the presence of elongated scattering particles with their long axes predominantly at right angles to the plane. According to L. Davis and J. L. Greenstein, this orientation may be caused by paramagnetic relaxation in a galactic magnetic field between 10^{-5} gauss and 10^{-4} gauss, if the particles have a small admixture of magnetic material.

Form of Absorption-Colour Curve and Nature of the Scattering Material.—The variation of the scattering coefficient from the violet to the red end of the spectrum has been studied

by comparing the brightnesses in various spectral regions of pairs of hot stars of identical spectral types seen through different degrees of obscuration. The most extensive measurements have been carried out photoelectrically (with colour filters) by J. Stebbins and A. E. Whitford (1943) and spectrographically by Greenstein (1938), C. Schalen (1952) and L. Divan (1951). The various results agree in showing that, in the limited range of wave lengths between λ 4000 Å and λ 8000 Å (roughly the visible range from violet to red) the scattering coefficient is nearly inversely proportional to wave length, but that the curve flattens off at both the ultraviolet and infrared ends. The absorption is thus neither neutral (as would be expected from large rocklike objects or from free electrons, neither of which could exist in sufficient quantities to explain the observations) nor is it in accordance with Lord Rayleigh's fourth-power law (which applies to atoms and molecules, *e.g.*, in the earth's atmosphere).

The absorption must arise from a fine dust or smoke with particles of dimensions comparable with the wave length of light (about $\frac{1}{20,000}$ cm.). Van de Hulst has shown that the observed data, including the polarization of starlight observed through obscuring matter, are consistent with a distribution of dielectric grains (probably consisting of ice with admixtures of solid hydrogen, methane, ammonia, metallic oxides and metals) having a typical diameter of 0.56μ (μ = micron: 1 micron = 10^{-4} cm.).

INTERSTELLAR GAS CLOUDS

Interstellar Absorption Lines.—Many distant, hot stars show in their spectra certain characteristic absorption lines with a red or violet shift differing from that shown by the remaining lines of the spectrum. This is particularly conspicuous in the case of certain spectroscopic double stars which show "stationary calcium lines," first discovered in the spectrum of δ Orionis by J. Hartmann (1904). Hartmann noted that the H and K lines of ionized calcium in the violet show a constant-velocity shift, while the shift of the remaining lines goes through a cycle of variation every few days because of the orbital motion of the system. Hartmann recalled the behaviour of the exploding star Nova Persei 1901 in which the H and K absorption lines, and also the D lines of sodium in the yellow region, had remained sharp and fixed while the other lines underwent complex changes in position and structure; he concluded that these lines must, in the case of both stars, have been superimposed on the spectrum of the star proper by the passage of its light through a gaseous cloud in which calcium and sodium were present.

Afterward, M. L. Heger showed that the sodium D lines also remain stationary in δ Orionis, and high-dispersion spectra of this and other stars by T. H. Dunham and W. S. Adams revealed in addition stationary lines of potassium, titanium, neutral calcium and the diatomic molecules CH and CN. In cooler stars, these interstellar lines are hard to detect because of their blending with the corresponding lines in the star's own spectrum.

That the clouds which produce the interstellar lines are distributed throughout the galaxy and do not exist primarily in the neighbourhood of individual hot stars was first suggested by A. S. Eddington and confirmed from a study of numerous spectrograms in 1929 by Otto Struve, who showed that, on the whole, the intensity of the interstellar K line increases steadily with distance. In 1935, J. S. Plaskett and J. A. Pearce studied the velocities in the line of sight of numerous hot stars (which are distributed close to the galactic plane). They showed that, in a given direction, the velocities of individual stars increase in proportion to their distances, in accordance with Oort's theory of differential galactic rotation, and that the velocity shift of the interstellar K line generally corresponds to about one-half the velocity (and hence one-half the distance) of the star, as though the gas were uniformly distributed in the intervening space.

Later work with spectrographs of higher dispersion by C. S. Beals (1936), R. F. Sanford, P. W. Merrill and O. C. Wilson (1938) and Adams (1943) showed that the interstellar lines are often split into numerous very narrow components, each being the effect of a separate cloud of gas with its own characteristic motion. According to estimates by A. Blaauw and B. Strömgren, a straight line 1,000 parsecs long in the galactic plane may traverse about 10 clouds with a mean diameter of about 5 parsecs, a mean density of 10 hydrogen atoms (or 2.7×10^{-23} g.) per cubic centimetre and a mean velocity relative to the average of the surrounding stars of about 7 km. per second. The chemical composition of the clouds seems to approximate closely to that of normal stars, but their temperatures are very low (of the order of 100° K., *i.e.*, 100° C. above absolute zero or −173° C.), so that the constituent atoms and molecules are practically all in their state of lowest energy. The absorption spectra therefore consist entirely of resonance lines, only a limited number of which occur in the observable spectral range. In 1953, Guido Münch showed that around Perseus the interstellar lines from hot stars at very great distances (up to 3,000 parsecs) split into two distinct groups of components, arising from gas clouds in the next spiral arm out from the centre of the galaxy as well as in the arm in which we are situated.

In addition to the lines mentioned above, certain highly diffuse absorption bands many ångströms wide are produced, the strongest being centred on λ 4430 Å. Their origin is unknown, but they appear to be associated with the clouds of obscuring dust rather than with the interstellar gas in general.

Radio Emission by Cosmic Gas.—In 1932, K. G. Jansky found that cosmic noise at radio frequencies was received by a directional antenna pointed at the sky; he and G. Reber afterward showed that the radio waves came from the Milky Way, the strongest radiation being received from the direction of the galactic centre in Sagittarius. After 1945, a number of point sources of radio emission were discovered both within and outside the galaxy, but only in certain cases was it possible to identify these visually. One such source within the galaxy is the Crab nebula in Taurus, which is the gaseous remnant of the supernova observed from China and Japan in 1054. An extragalactic source is Cygnus A, which was shown by Baade and R. Minkowski in 1952 to consist of two colliding galaxies. In this case the stars simply pass one another with little interference because of their enormous distances apart, but the clouds of interstellar gas and dust collide with relative velocities of 1,600 km. per second and are in violent turbulent motion.

Weak radio emission has been detected from the sun (enhanced by sudden bursts during solar flares), from the galactic plane, from the galactic corona (a large, spherical, extremely tenuous region roughly embracing the globular clusters and concentric with the Milky Way) and from nearby extragalactic nebulae; but it is significant that the strongest sources always consist of ionized gas with violent internal motions. The evidence suggests that the chief cause of radio emission is the deceleration of electrons moving with velocities approaching that of light in a magnetic field (synchrotron radiation). These ionized, magnetized gas clouds also provide a likely mechanism for the production of some cosmic rays. In the case of the quiet sun and of ionized hydrogen clouds in the galactic plane, however, the radio emission is of thermal origin, as a result of the deceleration of electrons in the electric fields of nearby protons. In 1963, by scanning the frequency spectrum of radio emissions from Cassiopeia A, radio astronomers detected the hydroxyl (OH) ion in interstellar space for the first time. They estimated that interstellar space contains one hydroxyl ion to every 10,000,000 hydrogen atoms.

Interstellar Hydrogen and 21-cm. Radiation.—Although hydrogen is by far the most abundant element in the interstellar gas, as in normal stars, its spectral lines are not detectable optically except as emissions from those clouds (known as H II regions) that are close enough to hot stars to be ionized by their ultraviolet radiation. In this case the capture of electrons by protons leads to the production of energetically excited hydrogen atoms which then lose their energy by emitting radiation, some of which appears in the visible region of the spectrum. At a certain distance from such a star (depending on its size and temperature and on the density of the nearby gas), the ultraviolet radiation is completely broken down into quanta of lower energies and longer wave lengths, so that hydrogen is no longer ionized (this is the H I region).

In accordance with the theory developed by H. Zanstra and Strömgren, the transition takes place quite suddenly, so that the typical H II region is a well-defined sphere surrounding a hot star or a group of hot stars. Such H II emission clouds are prominent in photographs of spiral galaxies, in which they were formerly often mistaken for bright stars. They occupy only about one-tenth the space taken up by the neutral H I clouds which produce the interstellar absorption lines; their physical state resembles that of the diffuse nebulae, such as the great emission nebula in Orion, but they are of a considerably lower density.

The development of radio astronomy has provided an extremely powerful method of detecting neutral hydrogen in interstellar clouds from the transition at 1,420 mc. per second (λ 21.1 cm.), a possibility which was suggested by van de Hulst in 1944. Radio waves of this frequency are respectively emitted or absorbed by a hydrogen atom in its lowest energy state, when the directions of spin of the proton and electron change from parallel to antiparallel or vice versa. This hyperfine structure transition takes place very rarely, the mean life of an atom in its upper state being about 11,000,000 years; but the clouds of interstellar gas are so vast that detectable amounts of radio noise are emitted at this frequency. The 21-cm. radiation from the Milky Way began to be observed in 1951, first by H. I. Ewen and E. M. Purcell (Harvard), then by C. A. Muller and Oort (Leiden, Neth.) and shortly afterward by W. N. Christiansen and J. V. Hindman (Sydney, Austr.). By observing the velocity shift of the 21-cm. line and applying Oort's theory of differential galactic rotation, van de Hulst, Muller and Oort plotted the spiral structure of the galaxy in the range of galactic longitude from 0° to 220°, while further spiral arms were detected in the southern Milky Way by Christiansen and Hindman.

In 1956, the 21-cm. line was detected in absorption from cool hydrogen clouds surrounding the intense radio source in Cygnus by A. E. Lilley and E. F. McClain, who showed that the recession velocity deduced from the Doppler shift of this line was in excellent agreement with the value of 16,700 km. per second measured in the optical spectrum by Minkowski. This result is strong confirmation of the view that the red shift observed in the spectral lines of distant galaxies is a true velocity shift.

Relationship Between Stars and Interstellar Material.—The distribution of interstellar gas and dust clouds is very heterogeneous, but roughly speaking they are confined within a distance of about 100 parsecs from the galactic plane (in the solar neighbourhood) and within the galactic spiral arms, which have a width of the order of 500 parsecs within the plane. While the dust appears to be confined to discrete clouds, which coincide with local concentrations of the gas with a density of about ten hydrogen atoms per cubic centimetre, there appears to be in addition a uniform distribution of gas with a density of about one hydrogen atom per cubic centimetre throughout the galactic disk. The temperature of the interstellar medium depends somewhat on the local intensity of stellar and cosmic radiation, but mainly on the absorbing properties of the medium; in H II regions it is about 10,000° K., in H I regions about 60° K. and the solid particles may be still cooler.

In the H I clouds there may be a statistical equilibrium between the gas and the dust grains, the latter being formed by combination and condensation and evaporated again by collisions between the clouds. The close association between bright, hot stars (which exhaust their nuclear energy sources so rapidly that they can be no more than 10,000,000 years old) and interstellar matter suggests that stars are being continuously formed by condensation from clouds of gas and dust. Possibly we are actually witnessing such a process in the T Tauri variables, stars which show emission spectra and are often accompanied by a visible nebulosity. The explosions of novae and supernovae and the slower ejection of matter from stars with expanding gaseous envelopes tend to replenish the interstellar medium, but only partially, since a certain fraction remains permanently locked up in white dwarfs. Thus the amount of interstellar material may be expected to diminish slowly with time.

At present the mean density of interstellar matter in the solar neighbourhood is about 3×10^{-21} g. per cubic centimetre, which is about equal to the density of material in the form of stars; but in the galaxy as a whole, most of which consists of relatively inconspicuous stars and of globular clusters distributed more or less spherically about the centre, the interstellar medium probably contributes only a small percentage of the total mass.

INTESTATE SUCCESSION. Upon the death of a person who has made a valid last will or testament, his property passes in accordance with his testamentary disposition. But if he has not made a will, or if his will is legally defective, or insofar as he has not validly disposed in it of all his property, the course of inheritance will be determined by the law of intestate succession. The development and problems of the law of inheritance in general are discussed in the articles INHERITANCE; ESTATES, ADMINISTRATION OF; PROBATE; and those of the law of wills in the article WILL. The present article is concerned with the problems of the law of intestate succession.

History.—Rules of intestate succession became necessary with the development of individual ownership in objects that would not, as in earlier stages of civilization, be destroyed at the death of the owner, or buried with him, or given away. However, the only statement that can be made about intestate succession in general is that it seems to have universally occurred within the kinship group and that its course has thus been determined in any given society by the form of its kinship organization. In most primitive societies the clan appears to have been the basic form of social organization, but there are also societies in which the nuclear family of mother, father and children is not overlaid by a clan organization and thus constitutes the basic social unit, as it does in modern western society. In its structure the clan, which consists of a number of households, can be organized matrilineally or patrilineally. In the former a person is regarded as related to only those persons whose descent is traced through his mother, while in the latter relationship through the father is decisive.

In a clan-organized society succession to status and thus inheritance to property are, on principle, limited to clan members. In reality, affections engendered by close community, especially of the household, have also influenced the course of inheritance. In a matrilineal society a man may have greater affection for the children of his wife than for those of his sister, and will thus be inclined to let them succeed to at least some of his goods. Social tensions resulting from such modifications of unilateral organization have been reported from various societies; for instance, the Ashanti of west Africa and the Trobriand Islanders of Melanesia.

It seems indeed that certain kinds of goods frequently are inherited patrilineally even though the bulk may descend matrilineally, or vice versa. An example typical of many primitive societies is presented by the Herero of South-West Africa, where secular property is inherited within the matrilineal clan while certain sacred cattle are inherited patrilineally. A system of consistently matrilineal inheritance is that of the Nayar caste of southern India, where a woman's husband does not enter her clan, has no rights over her children, and property devolves from a male to his sister's children.

Almost consistently patrilineal, on the other hand, was inheritance in Rome in the early centuries of the republican era, beginning about the 5th century B.C. Roman society at that time consisted of patrilineal clans (*gentes*) and patriarchally ruled "houses," the latter being called *familiae* but with a social role and organization different from those of a modern western-type family. Property was owned not by individuals but by families. In prehistoric times family ownership was probably conceived as ownership by the house as a group, similar to the joint family of Hindu society. In historical times it was conceived as ownership by the family chief, the *paterfamilias*. The paterfamilias was not only

the owner of all of the family's property but also the ruler of the group, which could be quite large. It comprised the wife of the paterfamilias; all his sons, irrespective of age, whose membership in the house had not been terminated by dismissal (emancipation) or adoption into another house; the wives of these sons and all of their male descendants, with their wives, who had not been emancipated or adopted into another house; and finally the unmarried daughters of the paterfamilias and the unmarried female descendants of the other members of the house.

When the paterfamilias died, those who no longer had anyone standing above them now became *sui juris; i.e.*, free of the dominion of another and capable of owning property in their own right. This was so for the widow, the unmarried daughters, those sons who had not been emancipated or adopted into other houses, and those grandchildren, great-grandchildren, etc., who had belonged to the house and whose father or grandfather had died or had been emancipated or adopted into another family. These persons were the "proper heirs" (*sui heredes*) of the deceased paterfamilias. At one time it seems that the house was continued under their joint headship. In historical times the house split up into as many new ones as there were heirs. Of the persons shown in Fig. 1, M, B, E and K became persons *sui juris* at P's death and thus his proper heirs.

If a paterfamilias died without being survived by any members of his house, the succession devolved to the "next agnate"; *i.e.*, the nearest relative related through males, or, more precisely, the person nearest to the decedent among those who would be under the same household power (*patria potestas*) if their common ancestor were alive. As illustrated in Fig. 2, the descendants of F, the father of the decedent, X, do not belong to X's agnates: brother B was emancipated and thus would not be under the power of F if F were still alive; sister S and her child N belong to the house, and are thus under the power, of S's husband B-L. Aunt A and her child are not agnates either, because they are under the power of A's husband, AH. The only agnates are second cousin SC and cousin C_2. Of these C_2 is one grade closer to X than SC; she would thus be the closest agnate, but as a female she was excluded from the succession by a law of 169 B.C. (*lex Voconia*). Therefore, SC would be the sole successor.

If the decedent was survived neither by *sui heredes* nor by any agnates, the succession devolved to the *gentiles; i.e.*, the persons who, as clansmen, could perform certain ancestral rites.

The known history of Roman law extends from the 5th century B.C. to the 6th century A.D. During that long period the importance of the clan declined with the growth of the power of the state; marriage ceased to result in the wife's subjection to the household power of her husband; and the tie of blood relationship came to be felt more vividly beyond the limits of agnatic relationship. The corresponding changes in the order of intestate succession were

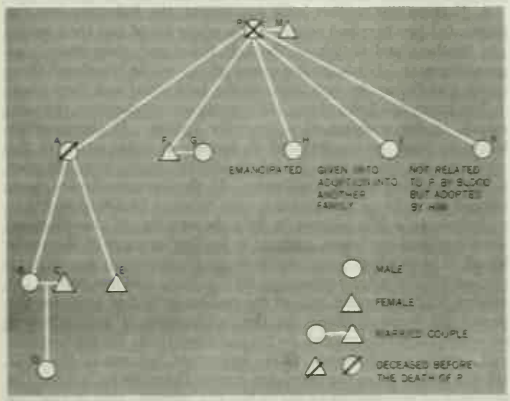

FIG. 1.—EXAMPLE OF SUCCESSION TO DESCENDANTS UNDER EARLY ROMAN LAW

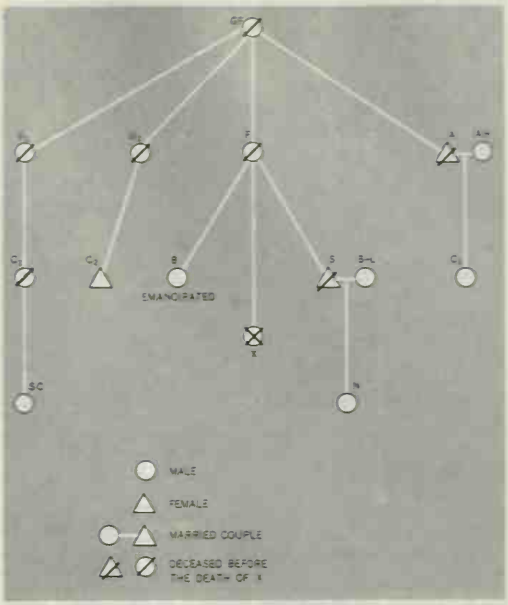

FIG. 2.—EXAMPLE OF SUCCESSION TO AGNATES UNDER EARLY ROMAN LAW

accomplished in a manner characteristic of Roman law. No formal change was made in the cherished rules of the ancient tradition, the *jus civile*, but the magistrate in charge of the administration of justice, the praetor, saw to it that a decedent's estate went to those persons who appeared to be entitled to it under the new order of things. In the time of early principate these persons were, first of all, the descendants of the decedent, including those who had been emancipated but not those who had been adopted into another family. If there were no such descendants, the succession passed, as in earlier days, to the nearest agnate. The more remote clansmen, however, were eliminated and their place taken by the nearest cognates; *i.e.*, the blood relatives in either the male or the female line. Finally, if there were no cognates, the property went to the surviving spouse, who, under the new system of marriage, was no longer a member of the husband's house. New changes were made by imperial legislation, culminating in Justinian I's *Novels* 118 and 127, of A.D. 543 and 548. The order that finally emerged was as follows:

1. Descendants, taking per stirpes; *i.e.*, by families, the children of any one descendant taking only the share that their parent would have taken if alive.

2. Ascendants, and brothers and sisters of whole blood, probably taking per capita; *i.e.*, sharing equally. If, however, the intestate had only paternal grandparents and a maternal grandfather, the latter took half. Nephews or nieces represented the brother and sister from whom they were descended.

3. Brothers and sisters of half blood.

4. In default of any relatives of the first three classes, the next of kin took per capita. Proximity of relationship was determined by counting upward from the decedent to the nearest ancestor common to him and the claimant, and then counting downward from that ancestor to the claimant. In Fig. 3, both A and B stand in the 5th degree of consanguinity to the intestate X, while C stands in the 6th degree. The estate is thus divided equally between A and B.

5. In default of any next of kin the estate devolved to the surviving spouse.

6. In default of all preceding classes the estate went to the imperial treasury, the fisc.

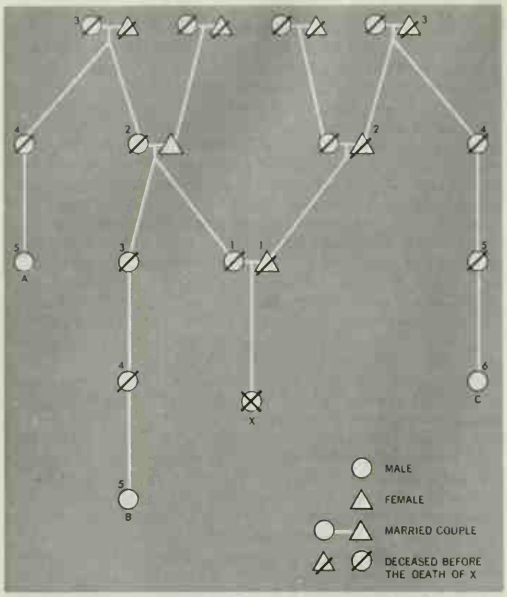

FIG. 3.—EXAMPLE FOR DETERMINING PROXIMITY OF RELATIONSHIP UNDER LATE ROMAN LAW OF SUCCESSION

Except for the position of the surviving spouse and some minor details, this order of intestate succession of the late Roman law is the same that prevails in most states of the United States. It passed into modern U.S. law through the medieval practice of the ecclesiastical courts of England, which was restated in the English Statute of Distribution of 1670. In England itself this system also prevails, but with important changes introduced by the Administration of Estates act, 1925.

While Anglo-American law, a system generally of Teutonic origin, has largely adopted the Roman order of succession, the laws of Germany and other continental countries, although strongly influenced by Roman law, have preserved important Teutonic traditions. Among the various systems that existed among the Teutonic peoples, two are still recognizable; one is that of the French civil code and the laws patterned on its model, the other that of the civil codes of Austria, Germany and Switzerland. In the former, the first order of heirs is constituted by the descendants; the second by the ascendants, the brothers and sisters of the intestate and their descendants; and the third by the collaterals, such as uncles, aunts and cousins, among whom the heirs are determined by counting degrees the same way as in Roman law. The surviving spouse ranks last, but is usually provided for through the system of community property (*q.v.*), by which he is entitled to one-half of what is usually the bulk of the property. The codes of Austria, Germany and Switzerland are based upon the so-called parentelic system. The first parentela or "line" of a person is constituted by his descendants, the second by his parents and their descendants, the third by the grandparents and their descendants, etc. However, under the Austrian code the right to inherit is limited to the first three parentelae and great-grandparents; under the Swiss code to the first three parentelae. No one standing in a more remote line can take if someone exists in a nearer line, and within each line a person standing closer to its head excludes the more remote ones. A varying portion of the estate is granted to the surviving spouse. In a modified form, the parentelic order was generally used in the medieval law of succession to land held in feudal tenure. In England this order was combined with the principle of primogeniture and in this form constituted the canons of descent of real estate held in freehold tenure, until it was abolished by the Administration of Estates act, 1925.

Modern Law.—Uniform rules of intestate succession to both real and personal property prevail in almost all common-law jurisdictions, generally patterned upon the system of the English Statute of Distribution of 1670 but diverging in matters of detail. Differences exist in particular with respect to the position of the surviving spouse, who may be entitled to a portion of the estate, or to a fixed minimum sum as in England and in several U.S. jurisdictions, or to a life estate in all or part of the estate, depending on who else survives the intestate.

United States.—In practically all U.S. jurisdictions the widow, and in some the widower and minor children, are entitled to an award to cover living expenses for the period (usually 9 to 12 months) during which the decedent's estate is wound up by the executor or administrator. In numerous states the surviving spouse is also entitled to a priority over both other heirs and creditors of the decedent with respect to a minimum portion of the land used by the family as its homestead.

In the community property states (Arizona, California, Idaho, Louisiana, Nevada, New Mexico, Texas, Washington) the community property is divided at the death of one spouse so that the surviving spouse has one-half, while the other half, together with the separate estate of the predeceasing spouse, passes under intestacy or under the will, as the case may be (*see* COMMUNITY PROPERTY).

While under the older law an illegitimate child had no rights of succession, modern acts generally provide for rights of intestacy between an illegitimate child and his mother and maternal relatives. A child who has been legitimated by the marriage of his mother and his reputed father or, as is possible in some U.S. jurisdictions, through acknowledgment by his reputed father, has the same position as a legitimate child. As to the intestacy rights between a person adopted, his adoptive parents, his natural parents and the relatives of the adoptive and the natural parents state statutes vary greatly (*see* ADOPTION).

If no relative of a decedent can be found, his estate escheats to the state. (M. RN.)

England.—The plan of distribution provided by the Administration of Estates act, 1925, was as follows:

1. A surviving spouse was to take the personal chattels absolutely and a net sum of £1,000. Of the residue of the estate, the surviving spouse took a life interest in half if the intestate had children or in the whole if he had none.

2. Subject to the rights of a surviving spouse, the estate was taken by the children at 21 or on marriage; the issue of children who had died taking at 21 or marriage their share of what their parent would have taken if alive.

3. If there was no issue, and again subject to the rights of a surviving spouse, the parents of the intestate took equally, or if one parent survived he or she took the whole.

4. If there was neither issue nor parent, the following was the order: (*a*) brothers and sisters of the whole blood and their issue; (*b*) brothers and sisters of the half blood and their issue; (*c*) grandparents; (*d*) uncles and aunts of the whole blood and their issue; and (*e*) uncles and aunts of the half blood and their issue.

The Intestates Estates act, 1952, made some important changes, mainly in the interests of a surviving spouse. If the intestate leaves no issue, no parents and no brother or sister either of the whole or the half blood, the whole of the residuary estate goes to the surviving spouse absolutely. If the intestate leaves issue, instead of £1,000 the surviving spouse receives £5,000 in addition, as before, to a life interest in half the residue; if the deceased leaves no issue but leaves a parent or brother or sister of the whole blood, or issue of such brother or sister, the surviving spouse is to receive £20,000 after payment of all liabilities, and one-half of the residue, while the other half of the residue is held in trust for the parent (or in equal shares for the two parents, if both survive) or, where there is no parent, on the statutory trusts for the brothers and sisters or their issue. Other important features of the 1952 act are that it gives the surviving spouse the right to call for the purchase or redemption of his or her life interest; that it modifies the law as to partial intestacies so that a surviving spouse obtains

a statutory legacy diminished by the value of any bequest; that it enables a surviving spouse, on certain terms, to acquire the deceased's interest in the matrimonial home; and that it applies the provisions of the Inheritance (Family Provision) act, 1938, as amended to an intestacy, so that a spouse, an infant child, an unmarried or incapable daughter or an incapable son may apply to the court for further provision out of the estate of an intestate.

(W. T. Ws.)

Scotland.—In the law of Scotland heritage (real property) descends to the heirs-at-law while the free movable estate (personal property) of the intestate is divided among the heirs *in mobilibus* who are the next of kin and those entitled to share in the succession under the Intestate Moveable Succession acts, 1855 to 1919. The heir of the heritable property, if one of the next of kin, must collate with the next of kin if he wishes to share in the movables. Proximity of kin is reckoned in the same order as in the case of inheritance. The Intestate Moveable Succession acts, among other changes, allow the issue of a predeceasing next of kin, not more remote than brothers and sisters, to come in the place of their parent in succession to an intestate; give the father of an intestate dying without issue one-half of the movable property in preference to brothers or sisters; and if the father and brothers and sisters be dead, a similar preference entitles the mother to succeed to the whole; brothers and sisters uterine are admitted in the absence of both brothers and sisters german or consanguinean and of father and mother. There are also rights of succession in both heritage and movables between a mother and her illegitimate issue under the Legitimacy act, 1926. *See* also SCOTS LAW. (J. WA.; X.)

INTESTINAL OBSTRUCTIONS. The alimentary tract digests and assimilates ingested food and disposes of the refuse. Any obstruction to the continuity of the bowel interrupts these three normal functions. Moreover, a blocked bowel often is accompanied by a chain of events that threatens life seriously. If the obstruction remains unrelieved, death follows.

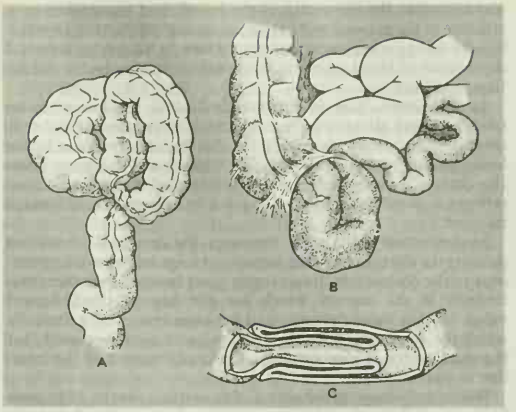
Causes.—The bowel may become obstructed through a number of agencies, of which the following types are recognized:

1. Congenital or acquired strictures of the bowel wall. Atresia and imperforation are types of congenital strictures that result from failure of the bowel to develop its lumen (canal) and are present at birth. Atresia usually concerns segments of the small intestine—duodenum, jejunum or ileum—though the proximal reaches of the colon may occasionally be involved. Ordinarily, the atresic area is a short segment an inch or less in length that looks like a fibrous cord. Imperforation concerns invariably the terminal end of the alimentary canal and involves only the anal canal and distal half of the rectum. Acquired types of stricture of the bowel that may give rise to obstruction are traumatic, inflammatory or neoplastic (cancerous) in origin. The first two are rare; strictures of the bowel caused by malignant growths are rather common, especially in persons past 45 years of age, and not infrequently give rise to obstruction, particularly in the colon.

2. Obstruction by obturation occasioned by the presence of a foreign body within the bowel lumen occurs occasionally. Fecal impaction is the most frequent variety of this type of obstruction. A large gallstone, ulcerating from the gall bladder into the small intestine, now and then causes obstruction by obturation.

3. Occlusions of the bowel may occur through the agency of compression by tumours outside the bowel, especially in areas where the bowel is fixed (*e.g.*, at the retroperitoneal duodenum or terminal ileum).

4. Adhesive bands are a frequent cause of intestinal obstruction.



FROM L. DAVIS, "CHRISTOPHER'S TEXTBOOK OF SURGERY," ED. 7; W. B. SAUNDERS CO., 1960

THREE TYPES OF INTESTINAL OBSTRUCTION: (A) VOLVULUS, OR TWISTING OF AN INTESTINAL LOOP; (B) CONSTRICTION BY ADHESIVE BANDS; (C) INTUSSUSCEPTION, OR THE TELESCOPING OF ONE SEGMENT OF BOWEL INTO ANOTHER SEGMENT

Adhesions are usually inflammatory in origin and follow in the wake of suppuration of the appendix, gall bladder and female generative organs (Fallopian tubes). Adhesions giving rise to obstruction often follow an abdominal operation. Ordinary talcum, with which surgeons formerly powdered their hands to facilitate pulling on of rubber gloves, is known to be a keen stimulus to adhesion formation, occasionally at a remote date after the operation.

5. Hernia (*q.v.*), or protrusion of a loop of bowel through a normal (inguinal, femoral, obturator, mesenteric or diaphragmatic) aperture or through an abnormal orifice (defect in abdominal wound following operation), is a common cause of obstruction.

6. Volvulus, or torsion of the bowel, may occur in the small intestine, caecum or sigmoid—areas in which a segment of bowel is pedicled on a narrow strip of mesentery.

7. Intussusception, or telescoping of one segment of the bowel into another, occurs most frequently in infants from four months of age through the first year of life. The cause is unknown. After two years of age, intussusception is relatively uncommon and a tumour such as a polyp, lipoma or cancer of the bowel is frequently found at the apex of the telescoped segment.

8. A number of miscellaneous congenital factors resulting from errors in development of the intestine may give rise to obstructions, among which the following may be enumerated: (*a*) anomalies of intestinal rotation; (*b*) extrinsic duodenal compression by congenital bands; (*c*) a persistent vitellomesenteric duct (Meckel's diverticulum) and umbilical eventration. In all of these, save the last, the obstruction may occur for the first time in childhood or even later.

9. Physiological imbalance in the nervous tone of the intestine may give rise to obstruction, which in this instance is often referred to as ileus. It may be paralytic (adynamic) in nature or spastic (dynamic). Spastic ileus mimics mechanical obstruction symptomatically. Peritonitis is the commonest cause of adynamic ileus. Deficiencies in the electrolyte (salt) pattern of the blood occasioned by loss of digestive fluids, either by vomiting or from severe diarrhea, may give rise to paralytic ileus. Notably, loss of potassium, chloride or sodium ions may be followed by a paretic state of the intestine, which can only be corrected by replacing the lost electrolytes.

10. Finally, thrombosis or embolism (plugging of the blood vessels of the mesenteric arteries or veins) may give rise to intestinal obstruction.

Consequences.—Whereas a number of different causes may be responsible for the development of bowel obstruction, there are essentially only two pathological types of obstruction: (1) simple

obstruction to the continuity of the bowel, best exemplified by a stricture in the gut wall and (2) strangulating obstruction, in which in addition to mechanical occlusion there is actual or potential deprivation of blood supply to the bowel (hernia, volvulus and intussusception).

In obstructions high in the intestinal canal, the loss of intestinal fluids and electrolytes through vomiting is frequent and constitutes an important element in the disease. Obstructions in the lower reaches of the small intestine (ileum) and the large intestine (colon) are attended regularly by intestinal distension because retrograde peristalsis and vomiting fail to evacuate the distended intestine.

In obstruction of the colon, moreover, the ileocaecal valve often delimits the distention to that segment of large intestine lying proximal to the obstruction, thus causing great hazard of rupture, particularly in the caecum, which lies just beyond the ileocaecal valve. It has been demonstrated by experiments on animals in which the opportunity for the swallowing of air is excluded that the chief source of gaseous distension in obstruction of the intestine is swallowed air.

Whereas students of intestinal obstruction prior to 1930 were likely to attribute the evil consequences of obstruction largely to abnormal permeability with absorption of noxious agents from the obstructed bowel, it later became more generally recognized that the ill effects of obstruction relate themselves essentially to the two items mentioned above: (1) loss of intestinal fluids and electrolytes by vomiting; and (2) the threatened loss of viability of the bowel wall occasioned by long-continued distention. With reference to the latter item, it is apparent that sustained intralumenal pressures maintained for some time above the mesenteric venous pressure (12 to 16 cm. of water) will interfere with the normal nutrition of the bowel wall. Anoxia or poor oxygenation of the bowel wall ensues in consequence of the arrest of venous outflow; as a result of anoxia, the bowel wall becomes devitalized. A bowel wall with impaired viability becomes abnormally permeable to noxious agents within its lumen, which now may migrate across the protective barrier of the damaged intestinal mucosa to the peritoneal cavity; from there, absorption occurs readily.

Recognition.—All mechanical varieties of obstruction (which make up by far the majority of all obstructions) are heralded by the presence of intestinal colic or "gas pains" occurring at the acme of an intestinal contraction or peristaltic wave. These contractions are accompanied by gurgling noises in the presence of a gut distended by both fluid and gas. The intestinal colic of gaseous distension (largely swallowed air) is accompanied by high-pitched sounds that usually have a metallic character. The noises (borborygmi) that accompany such contractions of the bowel are regularly attended by pain that is concurrent with the borborygmus, unlike the noise of the unobstructed gut, which is not accompanied by pain. These noises may be audible to the unaided ear but are elicited more readily on auscultation of the abdomen with a stethoscope.

Recurrent crampy abdominal pain with concurrent intestinal noises is synonymous with intestinal colic. Food indiscretions and the taking of a cathartic may simulate the intestinal colic of intestinal obstruction; however, the conditions they produce can be distinguished from mechanical obstruction by the absence of distension, their history and observation.

Strangulating obstruction, unlike simple obstruction, regularly is attended by abdominal tenderness. Percussion reveals the presence of tympanitic areas caused by the distended intestine, and a scout X-ray film of the abdomen indicates the extent and location of the distended intestinal coils.

An experienced observer summarizing these various findings may therefore determine: (1) whether obstruction is present; (2) whether strangulating or mere interference with the continuity of the intestine is present; and (3) where the obstruction is. He cannot in many instances, without recourse to exploratory operation, determine the exact variety of obstruction present.

Treatment of Intestinal Obstruction.—The object of treatment is to relieve distension and to restore the continuity of the intestinal canal. In obstructions in which vomiting has been an important factor, replacement of lost fluid and electrolyte by the intravenous administration of physiological saline and glucose solutions is important. Sir Frederick Treves of London, who wrote an important monograph upon the subject of intestinal obstructions in 1899, stated: "Those who are enamoured of statistics could, I have little doubt, show that it is less dangerous to leap from the Clifton suspension bridge than to suffer from acute intestinal obstruction and decline operation." Operation is still the mainstay of therapy. Every strangulating obstruction must be operated upon to free the strangulated loop from the agent that threatens its viability. All simple obstructions, such as a stricture, in which the block to intestinal continuity is persistent, must of necessity be subjected to operation. However, in a fairly large number of instances suction applied to an indwelling duodenal or long intestinal tube may succeed in decompressing the distended segment. Obstructions that owe their origin to inflammatory causes, nervous imbalance (paralytic or spastic ileus) or intestinal adhesions not uncommonly may relent when the bowel is decompressed by an indwelling intestinal tube. Attempting to relieve obstruction by such a tube is hazardous in that the obstruction may be strangulating in type or the obstructive mechanism may continue unrelieved. When satisfactory decompression of the distended bowel has not occurred within 12 hours following the employment of suction attached to a long intestinal tube, an operation should be undertaken. Use of a long intestinal tube provided with a stylet and coiled spring in its wall, passed at operation via mouth and stomach into the distended reaches of the obstructed small bowel, often permits decompression without having to open the distended bowel at operation. After the obstruction has been rectified, the stylet is withdrawn and the tube is left *in situ* to drain the bowel until assurances of physiological continuity of the bowel are in evidence.

The necessity of transfusing blood into the veins of patients having strangulating obstructions is apparent; for under the motive force of systolic blood pressure, blood is pumped into the vessels of the bowel wall and becomes imprisoned in the strangulated intestinal loop, thereby causing loss of blood from the circulation with consequent shock.

The inhalation of high concentrations of oxygen has been advised on the assumption that, despite the low coefficient of diffusion of nitrogen, inasmuch as the gas in the distended intestine is largely swallowed air (80% nitrogen), the breathing of pure oxygen by the patient will succeed nevertheless in removing by exhalation small but definite increments of gas from the distended bowel. Whereas this therapeutic procedure is sound in theory, it operates so slowly that it has little merit in practice. Oxygen administered in a hyperbaric pressure chamber has been used both experimentally and clinically to accelerate decrease of gaseous distension. A mechanical block cannot be removed in this manner.

Prognosis.—Recognition of the presence of intestinal obstruction earlier in its course, a better understanding of the ill consequences of obstruction, improvement in surgical technique, the employment of suction applied to indwelling long intestinal tubes and better schemes of intubating the duodenum quickly—all of these agencies combined to reduce materially the hazards of intestinal obstruction. The mortality of the presuction era (1931) was in the neighbourhood of 40% to 60% in the best surgical clinics of the world. By mid-20th century, however, mortality was reduced to the range of 10% to 12% in surgical clinics with a special interest in the problem of intestinal obstruction. Improvement continued to be recorded in the 1960s. When technical improvements permit surgeons to treat intestinal obstruction accompanied by great distension with the same effectiveness with which they now deal with similar conditions in the absence of distension the present mortality of acute intestinal obstruction will again be reduced considerably.

INTESTINE: *see* DIGESTION; GASTROINTESTINAL TRACT.

INTESTINE, SURGERY OF. The intestine includes the following three anatomic entities of the gut from the stomach downwards: (1) duodenum; (2) small intestine; (3) large intestine. Although similar disease processes affect these three segments of bowel (*e.g.*, obstruction, perforation, infection and cancer), there is a marked difference in incidence, symptoms and surgical treatment. (*See* also GASTROINTESTINAL TRACT; GASTROINTESTINAL TRACT, DISEASES OF.)

Duodenum.—This short segment of intestine, about 9 to 11 in. long, lies between the stomach and the ligament of Treitz. The first portion is frequently involved with ulcer disease. Primary cancer of the duodenum, diverticula (outpouching), cysts, fistulas, inflammation, obstruction or perforation may occur but are uncommon unless related to ulcer disease. (*See* also ABDOMEN, SURGERY OF; GASTRIC AND DUODENAL ULCER.)

Small Intestine.—This portion of the intestinal canal is approximately 21 to 25 ft. long and extends from the ligament of Treitz to the ileocaecal valve. About 40% of the proximal bowel is known as the jejunum; the last 60% is called the ileum.

The commonest disease necessitating operation is obstruction of the normal flow of intestinal content (*see* also INTESTINAL OBSTRUCTIONS). Terms frequently used to describe obstructions include the following: ileus (from the Greek meaning "to twist" or "to roll," connoting colic), a broad term generally used to mean obstruction from any cause; paralytic ileus, failure of peristaltic activity; mechanical ileus, obstruction due to structural block, *e.g.*, adhesive band, hernia or intraluminal foreign body; strangulation obstruction, obstruction that not only occludes but also threatens to completely deprive the bowel of its blood supply; volvulus, a twisting or torsion of a loop of bowel that causes obstruction with or without strangulation; intussusception, the telescoping of one segment of bowel into another.

Approximately 8,000 deaths occur annually from mechanical obstruction of the intestines. Cramping abdominal pain, associated nausea and vomiting represent the classic symptoms. The diagnosis is usually confirmed by typical gas patterns seen on roentgen examination. Treatment consists of surgically relieving the obstructing process. This may be either simple, as severance of one adhesive band, or complicated, as excision of strangulated (dead) bowel with resuturing of the uninvolved ends of intestine.

Miscellaneous diseases of the small intestine that require surgery include regional enteritis (inflammation of bowel segments); traumatic tears of the intestinal wall; Meckel's diverticulum (an outpouching in the ileum); and rarely, benign and malignant tumours.

Large Intestine (Colon).—This portion of the gut is about 5 ft. long and is twice the diameter of the small intestine. Cancer is the most frequent indication for colon surgery. In the United States, about 35,000 persons die of colon cancer annually. The greatest hope for reduction of this problem is earlier diagnosis leading to earlier surgical removal. Less common, but not rare, disorders of the colon leading to operation include ulcerative colitis, diverticulitis and traumatic injury.

INTIBUCÁ, small department in southern Honduras, bordering El Salvador. Its area is 1,186 sq.mi., and the population (1961) was 72,981, of which 82% was rural. La Esperanza, the departmental capital and largest town, had only 1,959 people in 1950. Less than 35% of the department area is in farms, and only 18% of this is cultivated.

The principal products of Intibucá are wheat, corn, beans, cattle, hogs and handicraft articles. La Esperanza is famous for its hand-weaving industry. One second-class road connects La Esperanza with the Inter-Ocean highway. (C. F. J.)

INTRACOASTAL WATERWAY: *see* ATLANTIC INTRACOASTAL WATERWAY; GULF INTRACOASTAL WATERWAY.

INTROSPECTION, in psychology, is the process of observing the operations of one's own mind with a view to discovering the laws that govern the mind (Lat. *introspicere*, "to look within"). In a dualistic philosophy which divides the stuff of the natural world (matter, including the human body) from the contents of consciousness, introspection is the chief method of psychology. Thus it was the method of primary importance to the English school of philosophy—to Thomas Hobbes, John Locke, George Berkeley, David Hume, James Mill, John Stuart Mill, Alexander Bain and most of their contemporaries—as it was to the pioneers of the new experimental psychology, especially to Wilhelm Wundt, Oswald Külpe and E. B. Titchener.

To all these men the contents of consciousness appeared to be immediate experience: to have an experience was for them also to know that you have it, and in this sense introspection appeared to be self-validating; it could not lie.

Wundt and Titchener, as well as Külpe in his early years (1893), believed that introspection finds in consciousness only sensory materials—sensations proper, images which are centrally excited sensations, and feelings which closely resemble sensations. This view is known as classical introspection.

Many other psychologists, however, found other kinds of content in consciousness. Franz Brentano and Külpe in his later years were the most influential act psychologists who reported consciousness as constituted of both sensory contents and more impalpable acts.

Perpetual controversy about the results of introspection made it quite clear by 1920 that introspection is not infallible and, later, that its fallibility is due to the fact that it is not immediate but is an observational inferential process that takes time and is subject to errors of observation. This discovery came in with the rise of objective psychology and behaviouristics in America.

By 1940 both the concept of dualism and the word introspection had largely disappeared from scientific psychology, especially in the U.S., where behaviourism ruled. Though Gestalt psychology retained a dualistic philosophy, its leaders rejected introspection because the word was so closely identified with the classical form.

Actually the repudiation of dualism by modern experimental psychology led only to the surrender of the word introspection, not to the abandonment of the method. The general method (not classical introspection) is used without the name (1) in phenomenological description as the Gestalt psychologists used it, as the phenomenologists and existentialists—mostly in Europe—use it now, and as it is employed in the description of experience in perception (*see* GESTALT PSYCHOLOGY; PHENOMENOLOGY; EXISTENTIALISM); (2) in psychophysics, where are determined the relations of conscious events, usually of a sensory nature, to magnitudes of the stimulus, especially in the determination of the sensory thresholds and sensory scales (*see* PSYCHOPHYSICAL METHODS); and (3) in the protocols of patients as they describe their consciousnesses to psychiatrists and psychoanalysts, sometimes in free association on the psychoanalytic couch, sometimes in projective tests such as the Rorschach ink blots, where the subject, for diagnostic purposes, reports the train of thought aroused in him by an equivocal stimulus or situation.

See E. G. Boring, "A History of Introspection," *Psychological Bulletin*, vol. 50 (1953). (E. G. BOR.)

INTUITION is the power of obtaining knowledge directly, without recourse to inference or to reasoning. Two senses of the word must be distinguished, one of them ordinary and one technical, the technical differing from the ordinary in the respect that it refers to supposedly primary or self-substantiating and not alternative sources of knowledge. These senses are: (1) the acquisition of knowledge of matters of fact without reliance on the ordinary procedures of inquiry; (2) the acquisition of knowledge of a kind which cannot be obtained by inference (*e.g.*, the knowledge of the axioms and rules of inference employed in logic

and mathematics and of the principles of morals). There are in addition two further technical senses (3 and 4), as mentioned below.

1. In its colloquial sense, as in the phrase, "feminine intuition," the word is used to refer to the capacity for making rapid and accurate assertions about matters of fact in circumstances where reliance on the standard procedure of inquiry is ruled out. It is often, perhaps usually, exercised predictively, on such matters as the outcome of horse races, impending disasters or the behaviour of someone in a yet unrealized state of affairs. For final justification of a claim to knowledge about the future we have to wait for the actual outcome. But before the event one may be quite confident of the truth of one's prediction. This confidence may arise from the strength of the inference leading to the prediction. But it may be that one "just knows," that one is not aware of any inference supporting one's prediction; and in such cases one is making a claim to intuition of the event predicted. This claim is not substantiated by the correctness of the prediction; it may have been a lucky guess. It is only if a man's claims to knowledge in advance about a certain subject matter are regularly correct that a power of intuition can be ascribed to him. For there is then inductive ground for taking his conviction as a reliable index of the truth of what he is convinced about. The existence and unequal distribution of such powers are not difficult to explain. One may be sensitive to significant features of what is currently observable without being aware of the fact (*e.g.*, facial expression as an index of character). This sensitivity will depend in part on natural endowment (*e.g.*, acute hearing) and in part on thorough familiarity with the subject matter in question. In this sense, then, claims to intuition arise either from implicit inference or from lucky guessing. We can only tell which, and thus on which to rely, by waiting to see if the claims are borne out significantly often.

So intuition here is not an independent source of knowledge. It is either inferential knowledge in a disguised form or not knowledge at all but guesswork.

2. In its most familiar philosophical interpretation intuition is the power of obtaining knowledge which cannot be acquired by either inference or observation, reason or experience. As such it is thought of as an original, independent source of knowledge, since it is designed to account for just those kinds of knowledge which other sources of knowledge do not provide. Our knowledge of necessary truths and of moral principles has been explained in this way.

In the first place, some necessary truths, statements of logic and mathematics, can be inferred, logically derived, from others. But not all can: there must be some uninferred statements (*i.e.*, axioms). Furthermore, the interconnected character of the system, the derivability of statements from axioms, presupposes rules of inference. Now the truth of axioms and the validity of basic rules of inference cannot be established by inference, since inference presupposes them, or by observation, which can never establish necessary truths. So they are held to be objects of intuition. Axioms are ordinarily truisms, consequently self-evidence is taken as a mark of intuition. To "see" that one statement follows from another, that a particular inference is valid, enables one, it is said, to make an "intuitive induction" of the validity of all inferences of that kind. Other nonformal necessary truths (*e.g.*, "nothing can be red and green all over") are also explained as intuitive inductions: we are held to "see" a universal and necessary connection through a particular instance of it.

Second, moral philosophers, from Bishop Butler and the Moral Sense school to G. E. Moore and the Oxford moralists, have held that moral assertions record knowledge of a special kind. The rightness of actions (or, in Moore's case, the goodness of states of affairs) is discovered by a special moral faculty, seen as analogous to the power of observation (Moral Sense school, Moore) or the power of intuiting logical principles (Oxford moralists). This theory, like that which holds logical principles to be the outcome of intuition, bases its case on the self-evident and unarguable character of the assertions with which it is concerned.

Against both theories much the same argument can be brought forward. The "axioms" of logic and morality do not require for their interpretation a special source of knowledge, since neither record discoveries: rather they record resolutions or conventions, attitudes that we adopt toward discourse and conduct, not facts about the nature of the world or man. A further argument against the theory of moral intuition depends on the markedly discordant character of the deliverances of the supposed source of knowledge.

3 and 4. Two further technical senses of the word may be briefly mentioned. One, deriving from Kant, is that in which it is understood as referring to the source of all knowledge of matters of fact not based on, or capable of being supported by, observation; that is to say, of matters of fact which observation directly or immediately reveals. The other is the sense attached to the word by Spinoza and by Henri Bergson, in which it refers to supposedly concrete knowledge of the world as an interconnected whole as contrasted with the piecemeal, "abstract" knowledge obtained by science and by common observation.

Popper, article in *Proceedings of the Aristotelian Society*, vol. xx, supp. (1946); P. F. Strawson, "Ethical Intuitionism," *Philosophy* (1949). (A. M. Q.)

INULIN, a polysaccharide that bears to the sugar levulose (D-fructose) a relationship similar to that of starch to glucose. It is used in making bread for diabetics and in diagnostic tests of kidney function. Inulin occurs in many plants of the large family Compositae (*q.v.*) to which the elecampane belongs; it is especially abundant in tuberous roots such as those of dahlia and Jerusalem artichoke. Inulinlike substances from various sources have been given distinctive names such as graminin (from certain grasses), irisin (from iris), etc. Fine inulin forms a white tasteless powder, sparingly soluble in cold water, very soluble in hot water and insoluble in alcohol. Dilute mineral acids or the enzyme inulase convert inulin into levulose (D-fructose). In many plants inulin is detected by the spherocrystals that form on steeping tissue slices in strong alcohol. *See* CARBOHYDRATES. (F. C. SD.)

INVAR, an alloy of 36% nickel, small amounts of manganese, silicon and carbon (less than 1% total), and the balance iron, characterized by an extremely small thermal expansion. The average coefficient is 0.70×10^{-6} per 1° F. (0.8×10^{-6} per 1° C.) for Invar compared with 6.8×10^{-6} per 1° F. (11×10^{-6} per 1° C.) for steel (0° to 200° F.) (about −18° to 96° C.). In applying these alloys it is important to recognize that their expansivity is dependent upon the temperature involved. The range for lowest coefficient is −60° F. to 175° F. (about −50° to 80° C.). Invar is used where it is advantageous to avoid temperature compensation; *i.e.*, for absolute standards of length, thermostatic strip, rods and tapes for surveying, horological instruments, glass-to-metal seals and in radio, electronic and jet-engine components. The name Invar was selected by its inventor Charles Édouard Guillaume (*q.v.*) to express the invariability of its dimensions with heat. (R. A. LR.)

INVARIABLE PLANE, the plane through the centre of gravity of the whole solar system for which the total angular momentum of the system about any axis in the plane is zero. Although the positions of the orbital planes of individual planets are affected by the motions of the other bodies in the solar system, Pierre Laplace demonstrated that no motions within the system can alter the total angular momentum. Thus, aside from minute effects due to the attractions of distant stars, the orientation of the invariable plane is fixed in space. A fundamental reference plane for the solar system, it lies between the orbital planes of the two massive planets, Jupiter and Saturn, at an inclination of roughly 1° 35′–1° 39′ to the ecliptic (*q.v.*). (D. L. H.)

INVARIANTS. The notion of invariant arises as soon as a mathematical construct is subjected to any one of a given group of transformations; and a search is made for properties of the construct (inner geometric properties) that are independent of the transformations (frameworks, co-ordinate systems) used to survey the structure. Necessarily this general definition is only partially satisfactory, since the idea of invariant in the history of mathematics has not been static. This discussion will first give some

illustrative examples of invariants, then show how the idea developed during the 19th century and finally will survey some modern developments.

Examples of Invariants.—Consider the quadratic polynomial $f = ax^2 + bx + c$. The equation $f = 0$ defines two points on the x-axis, the roots of the equation, and although the values of the roots depend on the origin chosen for the co-ordinate system, the difference between the roots must be independent of the origin. If a new origin of co-ordinates is defined by means of the transformation $x = X + \alpha$, the quadratic form becomes $f' = a'X^2 + b'X + c'$, where $a' = a$, $b' = 2a\alpha + b$, and $c' = a\alpha^2 + b\alpha + c$. The difference of the roots of the quadratic equation $f = 0$ is given as

$$\text{difference} = \frac{(b^2 - 4ac)^{\frac{1}{2}}}{a}$$

In the transformed equation $f' = 0$ it is found that $b'^2 - 4a'c' = (b + 2a\alpha)^2 - 4a(a\alpha^2 + b\alpha + c) = b^2 - 4ac$, and therefore

$$\frac{(b^2 - 4ac)^{\frac{1}{2}}}{a} = \frac{(b'^2 - 4a'c')^{\frac{1}{2}}}{a'}$$

Clearly, this is an example of an invariant associated with a quadratic polynomial, under the group of translations along the x-axis.

With a binary quadratic form $ax^2 + bxy + cy^2$ the orthogonal transformation

$$x = X\cos\theta - Y\sin\theta$$
$$y = X\sin\theta + Y\cos\theta$$

(corresponding to a rotation of the (x, y)-axes about the origin) produces the form $a'X^2 + b'XY + c'Y^2$, where

$$a' = a\cos^2\theta + b\cos\theta\sin\theta + c\sin^2\theta$$
$$b' = -2a\cos\theta\sin\theta + b(\cos^2\theta - \sin^2\theta) + 2c\sin\theta\cos\theta$$
$$c' = a\sin^2\theta + b(-\sin\theta\cos\theta) + c\cos^2\theta$$

It is apparent that $a' + c' = a + c$; and it is also found that $b'^2 - 4a'c' = b^2 - 4ac$. Therefore, two invariants have been found associated with this binary quadratic form under orthogonal transformation. If one of these invariants is zero in one co-ordinate system, it will be zero in any other of the co-ordinate systems considered, and thus the vanishing of any one of these invariants expresses an inner geometric property of the construct. In fact, if $a + c = 0$, the pair of lines through the origin represented by the vanishing of the binary quadratic form are at right angles, and this property is preserved under rotation of orthogonal axes. If $b^2 - 4ac = 0$, the pair of lines are coincident in the given co-ordinate system, and also in any other. The question of whether there are any other invariants attached to this form will be discussed in a more general context later.

The idea of an invariant already appears in C. F. Gauss' *Disquisitiones Arithmeticae* (1801), in which the binary quadratic forms $f = ax^2 + bxy + cy^2$ are studied under the linear transformations $x = \alpha x' + \beta y'$ and $y = \gamma x' + \delta y'$ where $\alpha\delta - \beta\gamma = r$. The resulting forms are $f' = a'x'^2 + b'x'y' + c'y'^2$, and it is easily verified that the discriminant (or determinant, as Gauss called it) $D' = b'^2 - 4a'c' = r^2(b^2 - 4ac) = r^2D$. In number theory the case for which a, b, c, d, α, β, γ, δ are all integers, with $r = 1$ (unimodular transformation) is of special interest. Conditions satisfied by the coefficients of the forms are sought that will permit one form to be transformed into another; this is the problem of the equivalence of forms. The condition $D' = D$ is a necessary, but by no means sufficient, condition. The discriminant is a relative invariant under the general linear transformation, and an absolute invariant under the unimodular transformation (*see* NUMBERS, THEORY OF: *Representation by Forms*).

Nineteenth-Century Developments.—The classification of binary quadratic forms just mentioned has a considerable background in geometry, and the subsequent development of invariant theory was influenced even more by geometrical considerations, induced by the study of projective geometry. The great British triumvirate of A. Cayley, G. Salmon and J. J. Sylvester, the Germans A. Clebsch and P. Gordan among others and the Italians F. Brioschi, L. Cremona and E. Beltrami all helped in this development. The founding of *Mathematische Annalen* in 1868, and the many papers published therein from numerous countries, reflected the improvement of communications among mathematicians; invariant theory especially flourished in this epoch.

The notion of determinant (*q.v.*), first mentioned by G. W. Leibnitz, developed by A. Vandermonde in the 18th century and A. L. Cauchy in the 19th century as an effective mathematical instrument, and brought to its full fruition by K. G. J. Jacobi is fundamental in classical invariant theory. The major properties of determinants were commonly taught in mathematics courses above the elementary level in the 1960s. The determinant

$$\begin{vmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ \cdot & \cdot & \dots & \cdot \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{vmatrix} = |a_{ik}|$$

is a simultaneous invariant of the n linear forms $\Sigma a_{1i}x_i$, $\Sigma a_{2i}x_i$, . . . , $\Sigma a_{ni}x_i$. This means that if the substitution $x_k = \Sigma\alpha_{kl}y_l$ is made so that the n linear forms transform into $\Sigma a'_{1l}y_l$, $\Sigma a'_{2l}y_l$, . . . , $\Sigma a'_{nl}y_l$, then the new determinant $D' = |a'_{ik}|$ is connected with the old $D = |a_{ik}|$ by the equation $D' = rD$, where $r = |\alpha_{ik}|$ is the determinant of the substitution. This follows immediately from the law of multiplication for determinants. The determinant is a relative invariant under the general linear transformation.

Generalizing the notion of linear transformation used so far results in what are called functional determinants. Here, n differentiable functions $f, g, h, \dots$ of $x_1, x_2, \dots, x_n$ are considered in forming the determinant

$$\begin{vmatrix} f_1 & f_2 & \dots & f_n \\ g_1 & g_2 & \dots & g_n \\ h_1 & h_2 & \dots & h_n \\ \cdot & \cdot & \dots & \cdot \end{vmatrix}$$

of partial differential coefficients where $f_i = \partial f/\partial x_i$. The relations $\partial f/\partial y_i = f_1\partial x_1/\partial y_i + f_2\partial x_2/\partial y_i + \dots + f_n\partial x_n/\partial y_i$, with similar relations for $g, h, \dots$, together with the multiplication law for determinants, show that this determinant of partial derivatives is invariant under the assumed set of transformations. The vanishing of this invariant expresses a more complicated inner geometrical structure: that of functional dependence of the set of functions $f, g, h, \dots$. The necessity is easily established since, if there exists a functional relationship $\phi(f, g, h, \dots) = 0$, it yields the n linear equations $f_i\partial\phi/\partial f + g_i\partial\phi/\partial g + h_i\partial\phi/\partial h + \dots = 0$, and the determinant of the coefficients of these n linear equations is 0.

If a form $f(x_1, x_2, x_3)$, homogeneous of degree n in the variables x_1, x_2, x_3 is considered, then $f = 0$ is the equation of a plane curve. Associated with this curve is the Hessian (functional determinant)

$$H = \begin{vmatrix} f_{11} & f_{12} & f_{13} \\ f_{21} & f_{22} & f_{23} \\ f_{31} & f_{32} & f_{33} \end{vmatrix}$$

(named after L. O. Hesse), where $f_{ij} = \partial^2 f/\partial x_i\partial x_j$. This curve is invariantly associated with the original curve, and since this Hessian determinant contains the variables x_1, x_2, x_3, it is called a covariant of the form f. The curve $H = 0$ can be shown to cut $f = 0$ in the inflexions of the latter curve. Hesse made a detailed study of the plane cubic and quartic curves, his aim being to express geometric properties of the curves by means of invariants and covariants.

The study of the invariants of curves and algebraic varieties of higher dimension under the group of birational transformations arose naturally in Italy and Germany in the later 19th and early 20th centuries. Mention need only be made here of M. Noether, and the three Italians C. Segre, G. Castelnuovo and F. Enriques; the subject of algebraic geometry (*q.v.*) that they initiated was taking on new life in the 1960s.

Consider now the invariants of quadratic forms under the group of regular linear transformations. A quadratic form $\sum_{i,k=1}^{n} a_{ik}x_ix_k$ ($a_{ik} = a_{ki}$) is a natural generalization of the ternary quadratic forms $ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy$ studied in the theory of conic sections, the consequential changes in notation deriving from the growth of matrix theory (*see* MATRIX) and the double-suffix notation for the position of an element in a given row and

column. Associated with any quadratic form $\Sigma a_{ik}x_ix_k$ there is the symmetric matrix $[a_{ik}]$. The problem of the equivalence of quadratic forms is bound up with the rank of their representative matrices. If two quadratic forms have matrices of the same rank, then a suitable linear transformation will take one form into the other. This assumes that the underlying field of numbers is such that the square root of any given number in the field also lies in the field.

For linear transformations over such a field, the rank is the only invariant of a quadratic form, and this integer describes the geometric complexity of the algebraic variety $\Sigma a_{ik}x_ix_k = 0$. For example, if $n = 3$, and the rank is 3, the curve represented is an irreducible conic. If the rank is 2, the curve is a pair of straight lines, and if the rank drops to 1, the curve is a pair of coincident lines.

For linear transformations over a real field, the situation changes. The given quadratic form can be transformed into $z_1^2 + z_2^2 + \ldots + z_s^2 - t_{\overline{1}}^2 - t_{\overline{2}}^2 - \ldots - t_{\overline{r-s}}^2$. The total number of squares r = rank $[a_{ij}]$, but now the total number s of positive squares (or $r - s$ of negative squares) is an invariant also, and under real linear transformations real quadratic forms have two numerical invariants; this is called Sylvester's law of inertia. Once again the inner geometric properties of quadratic varieties over a real field depend on their two invariants.

Now consider invariants from a slightly more general point of view. This discussion has been dealing with quantities with n components $x = (x_1, x_2, \ldots, x_n)$. These are called vectors, and their ambience is an n-dimensional vector space. Let there be given a group Γ of linear transformations A in an n-dimensional vector space P. A function $f(x, y, \ldots)$ depending on a number of argument vectors $x = (x_1, x_2, \ldots, x_n)$, $y = (y_1, y_2, \ldots, y_n), \ldots$ in P will change into a transform $f' = Af$ if $x, y, \ldots$ are sent by the linear transformation A into $x' = Ax$, $y' = Ay, \ldots$; this gives $f'(x', y', \ldots) = f(x, y, \ldots)$. If $Af = f$ for all substitutions A of the group Γ, the function f is called an invariant of Γ.

This concept may be illustrated by considering the symmetric group of linear transformations (*see* GROUPS; GROUPS, TRANSFORMATION). Symmetric functions $f(x_1, x_2, \ldots, x_n)$ of n arguments $x_1, x_2, \ldots, x_n$, that is, functions invariant under the group π_n of all $n!$ possible permutations of the n arguments, occur frequently in the theory of algebraic equations. These permutations are obviously linear transformations of the n-dimensional vector $x = (x_1, x_2, \ldots, x_n)$. The so-called elementary symmetric functions $\phi_1, \phi_2, \ldots, \phi_n$ are the coefficients of the polynomial $\phi(t)$ where $\phi(t) = (t - x_1)(t - x_2)\ldots(t - x_n) = t^n - \phi_1(x)t^{n-1} + \phi_2(x)t^{n-2} - \ldots \pm \phi_n(x)$ has the roots $x_1, x_2, \ldots, x_n$. Here, the following relations obtain:

$$\begin{aligned}
\phi_1(x) &= \Sigma x_i \\
\phi_2(x) &= \Sigma x_i x_k \text{ where } i < k \\
\phi_3(x) &= \Sigma x_i x_k x_l \text{ where } i < k < l \\
&\vdots \quad\quad \vdots \\
\phi_n(x) &= x_1 x_2 x_3 \ldots x_n
\end{aligned}$$

Any symmetric function of the vector x is, by our definition, an invariant of the symmetric group. The main theorem concerning symmetric functions is that they can be expressed in terms of the elementary symmetric functions $\phi_i(x)$. More explicitly, if $f(x_1, x_2, \ldots, x_n)$ is any symmetric function of the arguments $x_1, \ldots, x_n$, then there exists a function $F(\zeta_1, \ldots, \zeta_n)$ of the n arguments $\zeta_1, \ldots, \zeta_n$ such that $f(x) = F(\phi_1(x), \phi_2(x), \ldots, \phi_n(x))$. The functions $\phi_i(x)$ (where $i = 1, 2, \ldots, n$) are said to form a functional basis for the symmetric functions.

This is not a deep theorem if a function is being considered in the general sense. If the values of the $\phi_i(x)$ are given, the values of $x_1, x_2, \ldots, x_n$ are determined, except for their order, as the roots of $\phi(t) = 0$, and since the order does not affect the value of $f(x_1, \ldots, x_n)$, then $f(x)$ is determined by hypothesis, or is a function of the $\phi_i(x)$. But if $f(x)$ is a polynomial in $x_1, x_2, \ldots, x_n$, it is asked whether F is also a polynomial in $\zeta_1, \ldots, \zeta_n$. The main theorem for symmetric functions gives an affirmative answer.

Main Theorems.—The so-called first main theorem of general invariant theory is suggested by this example. This theorem says that all invariants are expressible in terms of a finite number among them. This is not true for all groups, but holds in the most important cases. The algebraic, as distinct from the functional, formulation of the dependence is, in all cases, the difficult part of the proof.

Another important group $\Gamma = O(n)$ of orthogonal transformations that is fundamental in Euclidean geometry provides a further illustration. Consider functions of two arbitrary vectors x,y that are invariant under all orthogonal transformations. The first fundamental theorem asserts that the scalar products that may be constructed for these two vectors, that is, the three products (xx), $(xy) = (yx)$ and (yy) form a basis. If $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$, the scalar product $(xy) = \sum_1^n x_i y_i$.

Now the functional part of this statement is merely the fundamental proposition about the congruence of triangles that says: the triangles ABC and A′B′C′ are congruent when two sides and the included angle of one triangle coincide with the corresponding elements of the other. In our notation, if two figures, each consisting of a pair of vectors x,y and x',y', are congruent, that is, transformable into each other by an appropriate orthogonal transformation, then it must be that

$$\begin{aligned}
(xx) &= \text{AB}^2 = \text{A}'\text{B}'^2 = (x'x') \\
(xy) &= \text{AB}\cdot\text{AC}\cos\theta = \text{A}'\text{B}'\cdot\text{A}'\text{C}'\cos\theta' = (x'y') \\
(yy) &= \text{AC}^2 = \text{A}'\text{C}'^2 = (y'y')
\end{aligned}$$

where θ is the angle between AB and AC, and θ' is the angle between A′B′ and A′C′. The algebraic proposition that every orthogonally invariant form $f(x,y)$ is expressible as a polynomial in the three scalar products is also true, but is a much deeper theorem.

To give more details of the first fundamental theorem for the orthogonal group, the result for the orthogonal invariants of an arbitrary number of argument vectors $x, y, \ldots, z$ is easily stated. A complete table of basic invariants is given by the symmetric matrix of all the scalar products

$$\begin{bmatrix}
(xx) & (xy) & \ldots & (xz) \\
(yx) & (yy) & \ldots & (yz) \\
\cdot & \cdot & \cdots & \cdot \\
(zx) & (zy) & \ldots & (zz)
\end{bmatrix}$$

If there are only the two vectors x and y, then the basic invariants (xx), (xy) and (yy), at least if the number of dimensions $n \geq 2$, are capable of all numerical values satisfying the inequality $(xy)^2 \geq (xx)\cdot(yy)$, corresponding to $\cos^2\theta \leq 1$, but otherwise the lengths of two sides of the triangle and the angle included may be assigned arbitrarily. From the algebraic standpoint, however, the quantities (xx), (xy) and (yy) are independent, since they are not bound by any algebraic relation.

The situation changes if the number h of independent vectors $x, y, \ldots, z$ exceeds the dimension n of the vector space. If there are $n + 1$ vectors $x, y, \ldots, z$, for example, they must be linearly dependent, and there is a relation $ax + by + \ldots + cz = 0$ among them. Forming the scalar product with $x, y, \ldots, z$ gives the $n + 1$ equations

$$\begin{aligned}
a(xx) + b(xy) + \ldots + c(xz) &= 0 \\
a(yx) + b(yy) + \ldots + c(yz) &= 0 \\
\cdot \quad\quad \cdot \quad\quad \cdots \quad\quad \cdot & \\
a(zx) + b(zy) + \ldots + c(zz) &= 0
\end{aligned}$$

and therefore the determinant

$$\begin{vmatrix}
(xx) & (xy) & \ldots & (xz) \\
(yx) & (yy) & \ldots & (yz) \\
\cdot & \cdot & \cdots & \cdot \\
(zx) & (zy) & \ldots & (zz)
\end{vmatrix} = 0$$

and the basic invariants are algebraically dependent.

The first major problem in the theory of vector invariants of a given group Γ is the determination of a set of basic invariants, and the first main theorem (that cannot, however, be asserted for all groups Γ) states the finiteness of such a basis. The second main problem consists in determining the totality of algebraic relations that hold among the basic invariants $\phi_1(x, y, \ldots)$, $\phi_2(x, y, \ldots)$, $\ldots, \phi_r(x, y, \ldots)$, or rather in finding a number of such relations of which all others are algebraic consequences. The finiteness of this number is the statement of the second main theorem. It holds for any group for which the first main theorem is true. This theorem, now to be considered, proves the existence of a finite num-

ber of relations, but in any given case the basis for the invariant relations still must be constructed.

The proof of the second main theorem is a special case of David Hilbert's famous basis theorem. Gordan, who had spent years in finding the bases for the invariant relations for various geometrical constructs, remarked of this very general proof: "This is not mathematics; this is theology." In fact, so general is Hilbert's work, inspired by invariant theory, that it nearly put an end to the theory of invariants.

Hilbert's theorem deals with polynomial ideals and proves that if k is any field, then every ideal in the ring of polynomials $k[\zeta_1, \ldots, \zeta_r]$ has a finite basis. Now, returning to invariants, all polynomials $R(\zeta_1, \ldots, \zeta_r)$ (relations) of r independent variables $\zeta_1, \ldots, \zeta_r$ that vanish after the substitution $\zeta_i = \phi_i(x, y, \ldots)$ identically in $x, y, \ldots$ form an ideal $\mathfrak{J}$ within the ring of the polynomials of the indeterminates $\zeta_1, \ldots, \zeta_r$. According to Hilbert's theorem, the ideal $\mathfrak{J}$ has a finite basis $R_1, \ldots, R_t$. All relations $R = 0$ that hold among the r basic invariants $\phi_i(x, y, \ldots)$ are thus consequences of the t relations $R_1 = 0, \ldots, R_t = 0$.

The General Concept of Invariant.—Finally, mention should be made of the general notion of invariant. The classical notion is usually concerned with a given group Γ of linear transformations A. The general notion is relative to a given abstract group $\gamma = \{s\}$ and a number of representations of γ of degrees $m, n, \ldots$, respectively: $\mathfrak{A} : s \rightarrow A(s)$, $\mathfrak{B} : s \rightarrow B(s), \ldots$. A function $\phi(x, y, \ldots)$ depending on an arbitrary quantity x of type $\mathfrak{A}$, another quantity y of type $\mathfrak{B}$ will be a certain function f of the numerical vectors $x = (x_1, \ldots, x_m)$, $y = (y_1, \ldots, y_n), \ldots$ in terms of a given frame of reference, and will be a certain function f' in another frame of reference in which the same elements have the components $x' = (x_1', \ldots, x_m')$, $y' = (y_1', \ldots, y_n'), \ldots$, and $\phi = f(x, y, \ldots) = f'(x', y', \ldots)$. If s is the transition from the first to the second frame, then $x' = A(s)x$, $y' = B(s)y, \ldots$, and the transform f' is denoted by sf. The function ϕ is an invariant if its algebraic expression f does not depend on the frame, so that $sf = f$ for all elements s of the group γ.

The generalization is on two fronts: the group considered is not necessarily the general linear group, or one of its subgroups, and the theory of group representations is the tool for the introduction of abstract groups, and the linking of the general theory to the elementary theory. Projective geometry (*q.v.*) so dominated the geometers of the first half of the 19th century that they tried to fit all geometrical considerations into the projective scheme. The emphasis on the group of transformations as the ruling principle in any kind of geometry came with F. Klein's Erlangen program (1872), presented in the paper *Vergleichende Betrachtungen über neuere geometrische Forschungen.* It is now clear that the study of the groups themselves and of their representations must necessarily precede the study of their invariants.

The theory of the representation of groups by linear transformations was created by G. Frobenius during the years 1896–1903. W. Burnside, independently, and I. Schur, in continuation of his work, found an essentially simpler approach by laying stress on the representing matrix itself rather than on its trace, the Frobenius character. Fundamental work in the modern development was carried out by J. H. M. Wedderburn and Schur soon after the turn of the century, and more recently by L. E. Dickson and A. A. Albert in the U.S. and E. Noether, H. Weyl and R. Brauer in Germany, and then in the U.S.

In summary, this has been a discussion of the classical theory of invariants. Additional coverage of the topic, including more recent developments relating in part to topology, may be found in ELASTICITY: *Theory of Strain;* GROUPS, CONTINUOUS: *Invariants of an Exterior Differential System;* TOPOLOGY, GENERAL: *Topological Properties.*

INVENTIONS AND DISCOVERIES. It is impossible to define "invention" with the breadth demanded by literary, scientific and legal usage. A poem, a musical composition, a theory which explains how light is transmitted from a source to the eye is as much of an invention as an electronic computer that solves in minutes problems that would ordinarily engage a mathematician for weeks. So is the universe of any cosmologist, ancient or modern. In this article technological inventions are the principal subject of discussion.

No sharp distinction can be drawn between invention and discovery. Gunpowder, a mixture of potassium nitrate, carbon and sulfur, certainly had to be discovered; yet it was also an invention. There are hundreds of such examples not only in chemistry but in engineering.

Discoveries often lead to invention. Thus the discovery that liquids expand and contract with variations in temperature led to the invention of the thermometer. Michael Faraday's discovery of electromagnetic induction was the basis of the telegraph, the telephone, the electric generator and motor, in fact of electric engineering. Conversely inventions often lead to discovery. Out of the steam engine came important theories that led to the development of thermodynamics and thus to more efficient steam engines. Out of Thomas A. Edison's electric lamp came the discovery that a feeble current could pass from the hot filament through empty space to a metal plate sealed in the bulb—the basis of the vacuum tube.

If the term "invention" is to be broadly defined as an act of the creative imagination, it is easy to understand why the French patent act of 1791, based on the Declaration of the Rights of Man and of the Citizen (1789), placed economic or social inventions on the same footing as mechanical and scientific inventions. Patents were therefore granted for tontine life annuities, tariff systems, credit plans, types of mortgages, banking systems, exchange controls and methods for guaranteeing the value of assignats. When it became apparent that there would be an avalanche of such schemes the national assembly on Sept. 20, 1792 decreed that the executive power should not only cease to grant patents for financial inventions but also to counteract the effect of those already granted.

The Inevitability of Invention.—Given a technical heritage and the right social environment, invention is inevitable. The phenomenon of simultaneous invention and discovery illustrates this. Alexander Graham Bell and Elisha Gray filed applications for telephones on the same day. Charles Martin Hall and Paul L. T. Héroult (1863–1914) discovered or invented the process of making aluminum independently and almost simultaneously. (*See* TELEPHONE; ALUMINUM.) Tessie du Motay (French) and Thaddeus Lowe (American) independently devised the process for making water gas by passing steam over red-hot coal; William Kelly and Sir Henry Bessemer, the one in the United States, the other in England, made steel by blowing air through molten iron to burn out the carbon (*see* CONVERTER STEEL). The history of invention and of the patent law is full of such examples and every year there are "interferences" in the United States patent office—judicial processes to settle rights of inventors who apply for patents on identical machines or processes. Since so many important inventions are conceived simultaneously and independently it is evident that inventive genius is not unique. In any community of 100,000 there are bound to be a certain number of ingenious mechanics, exceptional painters and fine musicians.

From this it almost follows that there are very few "first" inventions, in the sense that they owe nothing to earlier technical knowledge. Most of these must be credited to primitive man. Among them are the wheel, the bow and arrow, the fire drill, the boat, pottery, agriculture, domestication of animals, basketmaking. The melting of metals (gold, copper), the use of the lever, saw, wedge, pulley and rope are very old. Modern inventions as a whole are combinations of well-known elements that produce new results and serve new and useful purposes. Without a heritage technology could not advance. It was largely lack of a technical heritage that made it impossible for Leonardo da Vinci to invent a practical flying machine. For lack of a technical heritage Edison as a caveman would not have invented the phonograph, electric lamp and other devices with which his name is coupled.

How difficult it is to credit any inventor with having been the first in his field is shown by the history of the steamboat. About 30 steam-powered craft, more or less successful, had been built before Robert Fulton went up the Hudson river in his "Clermont" (1807). There was John Fitch who had a steamboat that ran on the Delaware river in 1787; Oliver Evans who built for Philadelphia in 1803 a combined scow and dredge which ran as a steam automobile on land and as a steamboat on the Schuylkill river; James Rumsey who began his experiments in the presence of George Washington; John Stevens who built a screw-propelled steamer in 1802; and William Symington, an Englishman whose "Charlotte Dundas" was a notable success (1802). The histories of the telegraph, the reaper, the motion picture, the filament electric lamp, the sewing machine and the elevator also shatter the pretensions of "first" inventors as a class.

Much, though not all, industrial progress followed discoveries made in the laboratory. Thus the discovery of the benzene ring by Friedrich August Kekulé emphasized the importance of molecular structure in organic chemistry and made it possible literally to design organic molecules with valuable properties. Similarly the mathematical development of the theory of the electromagnetic field by James Clerk Maxwell left it to be inferred that there is a broad spectrum of electromagnetic waves at one end of which lie light waves and at the other what were first called Hertzian waves after Heinrich Rudolf Hertz and later radio waves. Inventors of mechanical and electrical machinery apply such broad generalizations and theories, but the original discoveries or theories are not patentable.

Patent Legislation.—The Statute of Monopolies of James I of England, enacted in 1624, was designed to abolish privileges and monopolies which had become a public scandal. An exception was made of letters patent for the invention of new products. This dislike of monopolies as a whole and the exception made in the case of patents granted to inventions are part and parcel of the legal policy of the United States, Great Britain and other countries.

Patent legislation in the modern sense made its appearance toward the end of the 18th century. The constitution of the United States provided for the granting of patents somewhat after the British system but with the important stipulation that an application for a patent could be filed only by the inventor. In France, as noted above, patent legislation goes back to 1791. Before that the granting of patents was a royal prerogative. Some of the German states passed patent laws as early as 1815, but an over-all German patent law was not enacted until 1842. Most European countries followed the example set by the United States, Britain and Germany, some applying the British system, some the German.

Though Anglo-Saxon countries encouraged invention by the granting of patents it became apparent in the first half of the 20th century that there were as many objections to patent monopolies as to the trade and manufacturing monopolies that led to the promulgation of the Statute of Monopolies. In the United States large corporations may acquire literally several thousand patents to dominate an entire industry. This domination of a whole "art," as it is called in legal parlance, is opposed to Anglo-Saxon thinking on monopolies of any kind. Even in countries such as the United States, which are not socialistically inclined, the government is undermining the patent monopoly sometimes in direct violation of the patent law. The interests of the inventor are subordinated to those of society, with the result that in both Britain and the United States great corporations have been compelled to grant licences to those who want them, sometimes without the payment of royalties. Thus the United Shoe Machinery company was forced to grant licences under its hundreds of patents to all its competitors. Similarly the Aluminum Company of America had to relinquish monopolistic control of its many patents. Imperial Chemical Industries and du Pont de Nemours had to dissolve an agreement that was regarded as a cartel and to throw about 2,000 patents into the public domain.

By the second half of the 20th century, about 2,000,000 inventions had been patented in the United States. Prior to 1900 about 600,000 patents covering the first 110 years of the United States patent system had been granted. Most of these patents described inventions which lacked novelty or which were commercially impractical. (*See* PATENT.)

Encouragement of Invention.—Patent laws in general and those of the United States in particular were formulated on the theory that inventors should be encouraged, that inventive genius was rare, that society must await the coming of a Morse, Bell, Marconi or Edison before it could receive a new technological impetus, and that privileges in the form of limited monopolies should be granted to such men to make, sell and use their inventions as they saw fit in return for complete disclosure. The principle seems sound, yet the hundreds of thousands of patents granted in advanced countries leave no doubt that inventive ability is commoner than was generally supposed. Moreover, physicians, surgeons, engineers and professors of science invent many ingenious instruments and procedures that are never patented.

Some leaders of industry have attributed the remarkable rise of industry in the United States to the patent laws. There is no doubt that the patent laws have had a beneficent economic effect in exploiting rich natural resources, but after the earlier years of the 20th century sociologists and economists as a class discounted the encouragement-of-invention theory. Creative art stands on the same footing as creative mechanical invention. It can hardly be maintained that painters and poets need the spur of copyright laws to create, and copyrights, like patents, are intended to protect intellectual property rights. Frank William Taussig (1859–1940) in his lectures on *Inventors and Money-Makers* showed that inventors are much like artists and that the urge to create is so strong within them that they fly off at half a dozen tangents and too often fail to finish what they have begun.

Social and Economic Factors.—No doubt professional inventors are encouraged to invent by rewards in the form of profits. Yet a study of the lives of such inventors as James Watt, Samuel F. B. Morse and Alexander Graham Bell fails to reveal any convincing evidence that they derived the slightest encouragement from the patent system, though all patented their inventions. The profit motive is as strong as it ever was; yet for some reason the rate at which applications for patents have been filed has not kept pace with the rate of population growth. This decline has been international. The trend was the same in the United States, Great Britain, France, Germany, Canada and Japan; it indicated that something was happening to invention itself. That something could have been the increasing complexity of technology. An electronic computer which can solve a dozen simultaneous equations in a minute or two is hardly the type of invention that can be evolved by an ordinary mechanic who might design an improved reaping machine. The release of atomic energy by fission and the application of that release to the making of an atomic bomb could be expected only of highly trained theoretical physicists.

Whether or not a country is distinguished for its contribution to scientific discovery and invention depends on the social environment. Oriental countries played no important part in the development of modern technology, and yet the Arabs at one time were the most cultured and scientific people. In the Renaissance Italy led the world in science. In the early 18th century industrial supremacy passed to the northern countries, with Great Britain, Germany and the United States in the lead. It can hardly be maintained that one nation is naturally more inventive than another. The British, Germans, Swiss and Scandinavians have made quite as good a record in invention as citizens of the United States so far as quality is concerned, and in some branches of science they excel. The social environment is all-important because it determines what will be discovered and invented. This does not mean that society can dispense with men of exceptional ability or so-called geniuses, but it does mean that only when the social environment is favourable has ability the opportunity to express itself, whether or not there is a patent system.

That social pressure accounts for many important inventions and discoveries is proved by the events that brought about the Industrial Revolution (*q.v.*). After the introduction of the earliest steam engines and the substitution of coke for charcoal in the smelting of iron ore, coal was regarded as potential energy as well as a fuel. This brought about a profound change in outlook. Coal

ceased to be merely a fuel; it symbolized industrial might. With the invention of the gin by Eli Whitney, cotton became the most important of all textile fibres. Because of its leadership in metallurgy and in spinning and weaving, England was overwhelmed by the demand for yarns and cloths. The consequence was a further development of coke production and metallurgy to meet the demand for more and better textile machinery (chiefly power looms) and more steam engines to work mines and drive factory wheels. In the United States the introduction of Whitney's gin made it necessary to revivify the moribund institution of slavery because of the increasing demand for cotton pickers. Slavery became one of the issues of the American Civil War. The need of cloth woven in England from cotton exported by the southern states inspired the high-tariff policy of the Republican party as a protection for the spinners and weavers of New England.

In the later stages of the Industrial Revolution steam engines became more and more efficient, and the energy in coal was therefore more rationally applied. An invention that gave industry an impetus second only to that of the steam engine of Watt was the unpatentable system of interchangeable parts introduced in the United States by Whitney and Simeon North in the 1790s. The principle was old, but its application was the forerunner of standardization and hence of mass production by machine of countless articles ranging from automobiles to tins of vegetables, from bathtubs to electric lamps.

With the discovery in 1856 by William Henry Perkin of mauve, the first aniline dye, the rise of the coal-tar chemical industry began. It was the Germans who realized that Perkin's achievement meant as much for synthetic chemistry as did Watt's condensing steam engine for mining and manufacturing. Germany rapidly assumed leadership in synthetic chemistry and maintained it up to the outbreak of World War I. Out of German laboratories came thousands of chemicals derived from coal tar—dyes, photographic developers, explosives, drugs.

The history of the Industrial Revolution is an illustration of the effect of social and economic pressure on the inventor. Moreover, the Industrial Revolution also changed the character of invention. By 1900 the professional inventor appeared in the person of the scientist hired by an industrial corporation to improve old processes and machines and to invent new ones. For this innovation the Germans deserve a large measure of credit; the laboratories of their chemical industries demonstrated what could be accomplished by trained scientists and engineers, many of them former university professors, in transforming invention and discovery from a haphazard activity to an enterprise as systematic as manufacturing and selling. Germany's example was ultimately followed by the industrial nations of the west.

Revolutionary inventions have been usually conceived not within but outside an industry. Here and there are found a few spinners and weavers such as James Hargreaves (d. 1778) and Samuel Crompton who patented daringly new types of labour-saving spinning machines, but as a rule the inventors whose devices made it possible to spin and weave on a wholesale scale and to transfer yarn and clothmaking from the home to the factory were "outsiders," who neither made nor traded in textiles. Richard Arkwright, an illiterate barber and hairdresser, invented the spinning frame; Edmund Cartwright was a clergyman and poet when chance turned his mind to the invention of the power loom; Watt never concerned himself with steam engines until a model of a Newcomen pump was given him to repair; Whitney was not a cotton grower when he invented the gin but a young teacher who thought of becoming a lawyer; both Fulton and Morse were artists; neither Ottmar Mergenthaler nor Tolbert Lanston (1844–1913) were professional compositors when they patented the Linotype and Monotype.

Usually about 20 years has elapsed before an epoch-making invention has been successfully introduced commercially, partly because time and money must be spent in its perfection, partly because of the inertia of the institutions or individuals to whom the invention was offered. Hence the many tales, most of them untrue, of inventors who have all but starved to death before they succeeded in selling their inventions or finding financial backers as Watt did in Matthew Boulton or Bell in Gardner Hubbard. Too often the offered invention has been rejected, partly because its potentialities were not recognized, partly because of lack of energy and money to found a new industry. So patents in related fields accumulated until a venturesome promoter saw that they represented enormous wealth. Such is the history of inventing and patenting in the older industries.

Research.—No matter how it is conducted invention implies experimentation, hence research. The "heroic" theory of invention, the notion that an idea flashes from a brain and gives the world a sudden, fresh impulse must be dismissed. Watt's engine did not leap from his brain to the drafting board. New machine tools had to be devised by others to bore cylinders with the requisite accuracy; studies had to be made of heat losses; model after model had to be built in order to proportion moving parts and to determine the precise point at which steam might be cut off and used expansively. So it was with the Linotype, the typewriter, the phonograph, the incandescent lamp and many other devices and processes. Crude as was the experimentation that culminated in commercial perfection, it nevertheless deserved the name of research.

The laissez-faire policy of letting invention take care of itself gave way to organized industrial research. An important invention is an assemblage of known elements that produces a new result. Organized research hastens the process of accumulation, aggregation and combination; the salaried engineers, chemists or physicists of industry work contemporaneously in single establishments rather than separately decades or generations apart; correlation occurs simply, speedily and directly; time is telescoped. The "outside" inventor finds it more and more difficult to upset established manufacturing methods because he is likely to have been anticipated by industrial research scientists who know the technical literature of the field that they are exploring and who have at their disposal ample facilities for experimentation. By the second half of the 20th century about half the applications for patents in the United States were being filed by individual inventors; the other half were filed by research scientists and engineers in corporation laboratories or connected with such corporations. The acceleration in research was accompanied by an acceleration in the introduction of new inventions and discoveries. It took more than a century for the steam engine to establish itself, fewer than 50 years for electric energy, fewer than 30 years for the internal-combustion engine and fewer than 15 years for the vacuum tube; many applications of the transistor (*q.v.*), which was produced in the course of a modern industrial laboratory research program, were established within five years of its announcement. *See* also RESEARCH, INDUSTRIAL. (W. KT.; X.)

INVENTORY, a term used to designate items of property held in stock by a business firm. It includes items that are held for sale in the ordinary course of business, that are in the process of production preparatory to such sale, or that will be consumed in the process of producing goods to be sold. The term is also used in a more general sense to denote any list of property, such as that presented to a court by an executor, administrator or trustee, or that attached to a bill of sale. "Stocktaking" is the British equivalent of the U.S. term "taking inventory."

Inventories appear on a company's balance sheet (statement of financial position) as an asset and are of importance in determining the financial condition of a business. The money value of the inventory also appears on the income statement (sometimes known

as the operating statement or profit-and-loss statement) to determine the cost of the goods sold. To the inventory on hand at the beginning of the period is added the cost of purchasing and producing goods during the period; from this total is subtracted the inventory on hand at the end of the period to determine the cost of the goods sold during the period. As a rule, the larger the inventory at the end of the period, the greater the assets at the end of the year and the greater will be the income for the year.

Cost Methods.—For financial statements, inventories are usually priced (1) at cost; or (2) at cost or market value, whichever is lower. Both methods are considered acceptable by accountants providing consistent use is made of the method selected. Traditionally, financial statements are expected to be conservative in the sense that they understate rather than overstate the resources of a firm, and hence the lower valuation is more commonly used. For merchandise, materials and supplies, cost includes the amount paid or to be paid to the supplier plus cost of transportation and other payments necessary to bring goods to the place of business of the buyer. The cost of work in process and finished goods ordinarily includes the cost of the materials used in their production, the labour cost of production and other manufacturing costs (such as depreciation and insurance) which are associated with the goods in the inventory.

Determination of the cost of work in process and finished goods is the task of the cost accountant. Some cost accountants maintain that financial statements are more useful if only "direct costs," *i.e.*, material and labour, are included. Market value is generally calculated as the cost of replacement by purchase or production; sometimes market value is the selling price less the estimated costs of completing the manufacturing process and selling the goods.

The cost of the merchandise and materials purchased will ordinarily fluctuate during the year and it is therefore necessary to determine which cost is to be used for inventory purposes. Three methods are in general use: (1) average cost; (2) first in-first out (FIFO), which assigns the cost of the last units purchased to the inventory and the cost of the first units purchased ("first in") to the goods that were sold ("first out"); and (3) last in-first out (LIFO), where the reverse pattern is followed. The second of these probably describes the usual physical flow of goods because the old merchandise is usually sold first; the first describes it under some circumstances. Advocates of LIFO argue that this approach eliminates from reported income gains that have resulted from price changes; advocates of FIFO maintain that such gains should be reported.

Application of these procedures can be illustrated by the simple, though unrealistic, case of a merchant who bought one pair of shoes at $5 and later a second identical pair of shoes at $6. He sold one pair for $5.75. FIFO inventory cost would be $6; income (before deducting other costs of operation) would be 75 cents ($5.75 less $5 costs). LIFO inventory cost would be $5 and the loss (before deducting other costs of operation) would be 25 cents. The FIFO inventory cost may be said to represent the market value of the inventory; this will rarely be true of a LIFO cost. During a period of rising prices a firm using FIFO will show a higher income and larger assets; its financial statements are not directly comparable with a firm using LIFO. During such a period, the LIFO inventory firm will pay lower income taxes as a result of its lower income.

Turnover.—The "inventory turnover" of a firm is useful in appraising its financial position. An inventory turnover of six means that the goods are sold and replaced six times during the year, or that, on the average, each item remained in the inventory for two months. The inventory turnover for a retailer or wholesaler is calculated by dividing the cost of the goods sold during the year by the inventory. Calculation of the turnover of the inventory of a manufacturing firm is impossible; the ratio of sales (the total selling price of the goods sold) to inventory is usually substituted as a basis of comparison between firms. A high turnover indicates that goods are in stock a shorter period of time and hence that it will take less time to convert them into cash; the firm with a high turnover is therefore in a better position to pay its debts than one with a low turnover.

Managing the Inventory.—The physical quantity of goods on hand can be determined by a physical count by the employees of the firm or by maintaining a record of all increases (due to purchase or production) and decreases (due to sale or use in production). The former process is called a physical inventory; the latter a perpetual inventory. Even if perpetual inventory records are maintained, a physical count is usually made to determine that the goods are actually on hand; this verification process need not be done at one time—partial counts may be made all through the year.

The inventory is a valuable property of the firm and therefore needs to be safeguarded. To prevent diversion of the property from the business involves keeping a record of what should be on hand, the charging of an individual with the responsibility of seeing that the goods are used only for business purposes, and a physical count to see that the responsibility is discharged. The three functions—record keeping, safeguarding and physical counting—should be performed by different individuals. How much is spent on the physical control of inventories should depend on the type of goods in the inventory. Gold, for instance, requires many more safeguards than does coal. Perpetual inventory records, in addition to providing for the protection of company property, aid the management of the firm by making continuously available information as to the quantity of goods on hand. Some firms have adopted computer methods of stock control and verify their stocks every week.

The cost of carrying an inventory includes storage costs, insurance, possible deterioration and obsolescence and interest on the funds invested in the inventory; in addition the owner runs the risk of price declines. On the other hand, failure to have an adequate stock may result in loss of sales, inefficient use of manufacturing facilities and the cost of idle labour. Ordering or manufacturing in large quantities usually results in lower costs than ordering or manufacturing in small quantities. Decisions must therefore be made as to how large an inventory to maintain, when to order or to produce, and how much to purchase or produce. A firm ordinarily attempts to follow a procedure that will make the costs and losses connected with inventory as low as possible. This involves forecasts of the quantity that will be sold, the length of time for delivery and other factors. The inability to make perfect forecasts under changing conditions results in risks that every business must assume. (C. L. N.)

INVERARAY, a royal and small burgh and the county town of Argyll, Scot., stands near the mouth of the Aray, 9 mi. from the head of Loch Fyne and 58 mi. N.W. of Glasgow by road. Pop. (1961) 501. Created a burgh of barony in 1474, it became a royal burgh in 1648. As the ancestral seat of the Argyll family (*see* ARGYLL, EARLS AND DUKES OF), the town has figured largely in Highland history. When the 3rd duke built the modern castle in 1744–46 he transferred the town to its present site. Since 1957 the Historic Buildings Council for Scotland has modernized the houses internally, preserving externally the 18th-century architectural features. Notable buildings are the parish church, designed by Robert Mylne in 1794; Crombie's land, the birthplace of the novelist Neil Munro (1864–1930); the Town house, the traditional scene of the Appin murder trial (1753); and the Great tower with its peal of ten bells. A medieval Celtic cross stands near the pier. There is a tourist trade, forestry and farming. (DD. MACK.)

INVERCARGILL, the southernmost city of the Commonwealth of Nations, is the capital of Southland land district in South Island, New Zealand. It lies on the Southland plain on the Waihopai river near its confluence with the New river estuary, 139 mi. S.W. of Dunedin by rail. Pop. (1961) 35,605. The city is laid out on a rectangular plan with wide streets, those in the centre being named after Scottish rivers. Attractive public gardens and reserves include a central 200-ac. park. Invercargill is the centre of an important sheep and farming area and also serves as the base for the power generation project at Deep Cove. Most of the trade passes through the modern deepwater port of Bluff, 17 mi. S. Invercargill airport just south of the city is the terminus of the national trunk airline and is linked by amphibian services

with Stewart Island, 40 mi. S. The settlement was named after Capt. William Cargill, the Otago pioneer who founded it in 1856. It became a city in 1930. (L. A. Be.)

INVERCLYDE, BARON: *see* Burns, Sir George.

INVERELL, a town of northern New South Wales, Austr., lies on the Macintyre river 407 mi. N. of Sydney by road and 509 mi. by rail. Pop. (1961) 8,209. It lies at an elevation of 1,912 ft. in the west of the New England plateau. The district produces chiefly wheat and wool; cattle are raised and silver, tin, sapphires and diamonds are worked nearby. Inverell became a municipality in 1872. It is linked by air with Sydney and with Brisbane, Queensland. (R. A. Pa.)

INVERNESS, a royal and large burgh, seaport and county town of Inverness-shire, Scot., lies in the haughlands of the river Ness, which drains Loch Ness, at the eastern end of the great fault line known as Glen More. Pop. (1961) 29,773. The town is surrounded by hills on three sides and to the east the low lying shores of the Moray firth. Astride the river and the Caledonian canal (*q.v.*), it commands the route between the central Highlands and northern Scotland. The river estuary forms a good harbour with piers, breakwater and a slipway. From the quadrangle formed by the town centre, on the eastern bank of the river, the town climbs to the south to the Crown (residential) district and sweeps northward and eastward to the business and working quarters. Overlooking the river is the castle (1835), built on part of the site of a fortress blown up by Jacobites in 1746 and now housing the county law courts and other county offices. Beneath this stand the town hall (1882) and the fine old town cross (1685) let into the foot of which is the ancient Clach-na-Cudainn ("stone of the tubs"), once the resting place for women who carried water from the river. The town steeple (1791), near the town hall, was formerly a prison but now carries the town clock and bells. The Old High (parish) church (1769–72) has in its tower one of the bells removed by Oliver Cromwell from Fortrose cathedral. On the river's western bank, the residential area, is St. Andrew's Episcopal cathedral (1866–71) for the see of Moray, Ross and Caithness. The museum, in the Castle Wynd, houses a fine collection of Jacobite relics. A new bridge, replacing the suspension bridge, was opened in 1961. The picturesque Ness Islands about a mile above the town attract many visitors.

Since World War II light industries such as printing, picture post card printing, food canning and confectionery have been successfully introduced into Inverness. There is also highly specialized electrical and mechanical construction of heavy plant, steel mills and automobile components with a world-wide distribution. The herring industry occupies about 20 boats for five months of the year. The main imports are spirits and oils, coal, timber and cement. A small quantity of timber is exported.

The town serves as a railway and road centre; the airport at Dalcross, 8 mi. S.E., provides services to the Western Isles and to the south.

Inverness was one of the chief strongholds of the Picts and was visited by St. Columba (*c.* 565) with the intention of converting the Pictish king Brude, who is supposed to have resided in the vitrified fort of Craig Phadrick (Patrick's rock) 1½ mi. W. of the town. The castle is thought to have been built by Malcolm III (Canmore), after he had razed the one in which his father, Duncan, is said to have been murdered by Macbeth. It was a royal residence and fortress for centuries and saw a great deal of fighting. William the Lion (d. 1214) granted the town four charters, by one of which it was created a royal burgh. Hardly a trace remains of the Dominican abbey founded by Alexander II in 1233. On his way to the battle of Harlaw in 1411 Donald, lord of the Isles, burned the town, and 16 years later James I held a parliament in the castle to which the highland chiefs were summoned. The house, occupied in 1562 by Mary, queen of Scots, after she was denied admission to the castle, stands in Bridge street. At the northern end of the town Cromwell built a large fort, known as the Sconce, but it was practically demolished at the Restoration. (D. A. An.)

INVERNESS-SHIRE, the largest county in Scotland (4,211 sq.mi.), contains about a quarter of the Highlands and a quarter of the Western Isles. Between the Moray firth on the east and the indented Atlantic shore on the west lies the massive mainland portion bounded on the north by Ross and Cromarty and on the south and east by the shires of Argyll, Perth, Aberdeen, Banff, Moray and Nairn. More than one-third of the area consists of islands, including Skye, Raasay, the Small Isles (Rum, Eigg, Canna and Muck) in the Inner Hebrides, Harris, North and South Uist, Benbecula, Eriskay, Barra, etc., in the Outer Hebrides (*see* Hebrides, The), and the St. Kilda group.

NOEL HABGOOD

LOCH LAGGAN IN SOUTHERN INVERNESS-SHIRE, SOURCE OF THE SPEAN RIVER

Physical Geography.—The mainland portion is almost bisected by the fault-directed Great Glen (Glen More nan Albin), running northeast from Fort William to Inverness. In the narrower part, reaching the west coast between Glenelg and Glenshiel, a main erosion surface at 3,100–3,500 ft. has been deeply dissected by water and ice. Block mountains yield many conical peaks, while the structurally directed main glens running northeast, east and southeast contain many glaciated rock-basin lakes. West coast fjords are linked by low passes with easterly glens giving access to the Great Glen. The almost fjordlike Loch Morar actually contains fresh water and is the deepest lake in Britain, reaching 1,032 ft. below mean sea level. Postglacial raised beaches, preserved in sheltered places up to 100 ft., give level, well-drained, easily tilled fields in limited, narrow belts.

South and east of Fort William somewhat similar country in Lochaber is dominated by the massive lava-crowned granite boss of Ben Nevis (4,406 ft.). The "parallel roads" of Glen Roy in northern Lochaber are shoreline terraces marking successive levels of a glacially dammed lake. Eastward the block mountains are less dissected; gently sloping massive schistose hills alternate with broad glens or straths. To the northeast stands the high Cairngorm plateau, a major granite batholith with a considerable area over 4,000 ft. partly in Aberdeenshire and Banffshire. On the southern border is the main Grampian watershed, glacial breaching of which has chiselled Loch Ericht (14½ mi. long and at 1,153 ft.). From the Grampians the moorlands of Badenoch slope gently to the broad corridor of Strathspey or Speyside. North again the schistose Monadhliath mountains, reaching a summit plane of 3,000 ft., also follow the Caledonian northeasterly trend, as do the broad glens of the Spey Findhorn and the Nairn rivers. Northwest of the Monadhliath mountains a heavily glaciated plateau at 1,000–1,200 ft. gives way in a steep faultline scarp to the Great Glen, there occupied by Loch Ness, the biggest of the three glacial ribbon lakes in the Great Glen; its floor exceeds 600 ft. below sea level for over 17 mi. of its length of 22½ mi. North of the Great Glen are more broad glens trending east or northeast: Glen Moriston and Glen Urquhart, both among broad moorland plateaus of 1,500–2,000 ft.; Glen Affric, Glen Cannich and Strathfarrar, amid conical schistose hills reaching 3,000–3,300 ft. All these glens drain to the Strath Glass-Beauly lowlands, which merge with the raised beaches by the Beauly firth and Inverness firth.

The county's many Atlantic islands include the now uninhabited St. Kilda group about 40 mi. W. of North Uist, with their great

storm-swept cliffs and schist and granite hills; also the Outer Hebrides from Berneray in the south to the county boundary in the "long island" between Harris and Lewis, with their low hills of ice-scoured Archaean gneiss, innumerable glacial lakelets and hollows of boulder clay overlain with peat, and fertile western fringe of shellsand, the *machair*. Skye is the "winged isle" of peninsulas and varied scenery, from the jagged Black Cuillins of Tertiary gabbro to the lighter-coloured massive granite Red Cuillins. There are contrasts again in Rum, with its Torridonian sandstones and peridotites flanked by granites; while nearby Eigg, Muck and Canna are largely of Tertiary basalt.

Mild but windy winters prevail in lowlands in the western fringe and islands (January mean monthly temperatures 40–42° F.), with mean annual rainfall about 40 in., though higher near mountains. The mountains of the western mainland have 100–200 in. mean annual rainfall, while the hilly centre has harsh winters (30–100 mornings a year with snow lying). The eastern lowlands are sunny and dry (mean annual rainfall 20–24 in.), and particularly so, though cool, in the spring and early summer. Typical moorland vegetation in the wetter west is wet grass moor (purple moorgrass, sedges, etc.), with acid grasslands (fescue-purple moorgrass, with mat grass, heather and bracken) on drier sites there and in parts of the drier eastern plateaus. The dominant type in the latter is, however, heather moor. The highest hills have a zone of subalpine moor above which is arctic-alpine vegetation. There are residuals of the once widespread Caledonian forest, *e.g.*, in Rothiemurchus where there is a beautiful association of Scots pine, juniper and heather. (A. T. A. L.)

Red deer abound on the mountains of the mainland and islands, and a small herd of reindeer from Sweden was established in Rothiemurchus in 1952. The wild cat has re-established itself as the result of relaxed game preservation during two world wars. The eagle, gray lag goose, capercaillie and crested tit breed in some areas. After an absence of many years ospreys nested successfully in the Loch Garten bird sanctuary set up for that purpose in 1959. In the Cairngorms, Glen More national forest park (12,500 ac.) was established in 1948 and an area of 36,689 ac. (partly in Aberdeenshire) was in 1954 declared a national nature reserve. National nature reserves have been established in the Isle of Rum (1957), 26,400 ac.; St. Kilda (1957), 2,107 ac.; Loch Druidibeg, South Uist (1958), 2,577 ac.; and Craigellachie, Aviemore (1960), 642 ac.

History.—Stone axes and other weapons or tools dug up in the peat, and carvings such as the incised boar on a shale slab at Knocknagael near Inverness are evidence of early inhabitants. The Clava cairns and stone circles are among the best preserved of this type of burial place. Hill forts are widely scattered, with signs of vitrifaction at Craig Phadrick (Inverness), in Glen Nevis, Glen Garry, Arisaig and Kilmorack; the foundations of round huts mark the sites of early settlement; there are two fine specimens of brochs (dry stone towers) in Glenelg, and crannogs (lake dwellings) occur in some of the lochs.

When the country north of the Grampians emerged into history the Picts were in possession, and it was to Inverness, as the capital of their king, Brude, that Columba went on his Christianizing mission about 565. As Scotland gradually became united, the great province of Moray was formed, including a large part of the modern Inverness-shire as well as the counties to the east and north of it. Dynastic quarrels resulted in two waves of immigrant landowners, the first in the 12th century, the second in the early 14th. The first brought in the Mackintoshes and Bissets, and the second the Frasers, Chisholms and Grants. (The Chisholms, who have owned Strath Glass since the 14th century and whose seat was Erchless castle, gave their name to a pass in Glen Affric. Urquhart castle was the home of the Grants for 400 years from 1509.) In the west the Macdonalds, Camerons and Macleods remained under the sway of the Lords of the Isles, whose influence spread right across the mainland when the earldom of Ross was joined to the lordship. The 15th and 16th centuries, however, saw the Stewart kings attempting to exert their control over the whole country, and using the growing clan system as a means of bringing order to the north through the influence of the chiefs. In the 17th century the clans were divided by religion and politics: the duke of Montrose won a brilliant victory for the royalists at Inverlochy (1645) and Oliver Cromwell planted a garrison at Inverness. The Jacobite risings again set clan against clan: the revolution of 1688 was followed by the building of Forts George, Augustus and William (at Inverness, Kilchumin and Inverlochy); one of the steps toward pacification after 1715 was the building of military roads by Gen. George Wade (*q.v.*) and his successors; and the brief campaign of Prince Charles Edward (*q.v.*) in 1745–46 (begun at Glenfinnan and ended at Culloden, both within the county) was followed by the forfeiture of the Jacobites' estates, the abolition of the power of the chiefs and the proscription of the Highland dress. Economic factors put an end to the system of patriarchal rule, many of the chiefs had to sell out to strangers, sheep-farming was introduced on a large scale, and by the mid-19th century eviction and voluntary emigration had cleared many of the glens. The granting of security of tenure to crofters and other measures of relief has not, however, stemmed the drift from the rural areas.

Population and Administration.—At the first official census in 1801 the population of Inverness-shire was 72,672; it increased regularly until a peak population of 97,799 was recorded in 1841. At the 1961 census the population was 83,425, a decrease of 1,505 since 1951. Of the total, 65,004 were on the mainland, the highest number ever recorded, and 781 more than in 1951; while the island portion in the same period suffered a loss of 2,286. The density, three persons to every 100 ac., was about the same as in 1931 and 1951. Gaelic and English were spoken by 19,848 people (3,816 fewer than in 1951), and Gaelic only by 538 (470 fewer). The rural areas have lost population to the local burghs of Inverness, Fort William and Kingussie, as well as to other parts of Scotland.

With Ross and Cromarty, Inverness-shire returns three members to parliament—for Inverness, Ross and Cromarty, and the Western Isles. With Moray, Nairn and Ross and Cromarty, it forms a sheriffdom with resident sheriffs-substitute at Inverness, Fort William, Portree and Lochmaddy. The county council, with headquarters in Inverness, has 65 members representing nine districts (Inverness, Aird, Badenoch, Lochaber, Skye, North Uist, Harris, South Uist and Barra), each of which also has its own district council. For certain functions the county council also includes representatives of the burghs. For ecclesiastical purposes the county is divided into the presbyteries of Abernethy and Inverness (part of the synod of Moray), Skye and Uist (synod of Ross, Sutherland and Caithness) and Lochaber (synod of Argyll). Senior secondary education is provided in Inverness (whose Royal academy was founded in 1792), Fort William, Kingussie and Portree; a technical college was opened in 1960 at Inverness, where there is a branch of the North of Scotland College of Agriculture. The Royal Northern infirmary (1804) and Raigmore hospital are in Inverness, and there are others in Fort William, Skye and Uist. Two regiments having their depots in the county, the Seaforth Highlanders and the Queen's Own Cameron Highlanders, amalgamated as the Queen's Own Highlanders in 1961. Commando units were trained in Lochaber during World War II, and a monument to those who fell was unveiled near Spean Bridge in 1952. A guided-missile range has been established on South Uist.

The Economy.—Agriculture, forestry and fishing are the basic industries. With a small proportion of arable land, stock raising is important, store cattle raised on the higher land being fattened on the lower and more fertile ground, while sheep are the principal stock on the higher hills. Livestock also includes pigs, horses, goats and poultry. A single unit cattle breeding ranch established in 1947 at the southwestern end of the Great Glen, comprising about 100,000 ac., and large-scale hill farming at the northern end demonstrated the possibility of reclaiming unproductive land and providing winter feed for stock. The main crops are oats, barley and wheat; turnips and potatoes are the chief root crops.

Part of the old Caledonian forest extends for several miles near the Perthshire boundary and in Glenmore. Many famous forests were cut down during the two world wars, but natural woods are extensive, and considerable re-afforestation has taken place, partic-

ularly in Badenoch and the Great Glen. Private and state woodlands between them cover about one-tenth of the land area. More than 800,000 ac. are devoted to deer forest.

Mallaig and Fort William are the main centres of the herring and lobster fisheries, and fishing is also carried on in the Inverness firth and among the Outer Hebrides. There was a whaling station in Harris, and basking sharks were hunted commercially off the west coast and among the islands for some years after World War II.

Inverness is not an industrial county, but as the centre of large hydroelectric projects it is the source of power for others, and a number of small local industries have been established. The first major hydroelectric development in the United Kingdom was the Foyers station (near Loch Ness) of the British Aluminum company, opened in 1896 and followed by the Kinlochleven and Lochaber generating stations. Under the North of Scotland Hydro-Electric board, established in 1943, the county has projects at Morar (opened in 1948), Glen Garry and Glen Moriston, Glen Affric, and Strathfarrar and Kilmorack, besides smaller projects in Skye and Harris. Resistance welding machine construction is carried on at Inverness by the firm which made "Pluto" pipe lines in World War II, carrying oil across the English channel to Allied armies in Europe. There are distilleries at Inverness, Tomatin, Dalwhinnie, Fort William, Inverlochy and Carbost (Skye). Seaweed is processed in South Uist, and diatomite has been exported from Skye. Harris, Skye and other islands produce tweed. There is a deepfreeze food-preserving plant near Inverness. The tourist industry is of growing importance. Ben Nevis, with its diversity of rock conformations and panoramic prospects, attracts the climber (a race to the summit was first recorded in 1895); facilities for skiing in the Cairngorms have been developed; and pony-trekking was first introduced at Newtonmore in 1952. Deerstalking and grouse shooting attract visitors, and rivers and lochs abounding in salmon and trout provide sport to many anglers.

Communications.—Military roads were built in the Highlands under the supervision of General Wade between 1726 and 1732, those in the county forming three sides of a triangle—Fort George (Inverness) to Fort William, Dunkeld to Inverness over Drumochter, and Dalwhinnie to Fort Augustus over Corrieyarrick. Except for the last, which has been supplanted by the easier route by Loch Laggan to Spean Bridge, these are still the main lines of road communication in the county; improvements were made on the main north road in 1763, again by Thomas Telford (*q.v.*) in 1806–09 and also in the 1930s, when a new through road was also built on the west side of Loch Ness to improve communication through the Great Glen. Improvements have also been made in more remote areas, including the connection of Benbecula with South and North Uist by bridge and causeway.

The main railway line between Inverness and the south (via Edinburgh and Perth) enters the county through the Pass of Drumochter, 1,484 ft. above sea level and the highest main-line summit in Great Britain. This route was opened from Perth to Forres (with which Inverness had been connected since 1855) via Aviemore in 1863, the direct line by Carrbridge and Daviot following in 1898. The West Highland railway was opened to Fort William in 1894, to Banavie in 1895 and to Mallaig in 1901. There was a branch line to Fort Augustus from 1903 to 1946.

The Caledonian canal, built by Telford in 1804–12, includes 40 mi. of navigable loch in its total length of 60 mi., and there are 28 locks to carry it up to the level of Loch Oich, exactly 100 ft. above high-water mark at Inverness and Fort William.

There are regular steamer services between Kyle of Lochalsh (Ross), Mallaig, Skye and the Outer Hebrides.

There are airports at Inverness and Benbecula and a landing field at Barra.

INVERSION, in geometry, may describe the process of finding two points (on the diameter of a sphere or circle) the product of whose distances from the centre equals the square of the radius. In a more general case, suppose in the figure

that $OP = 1$, $OP_1 = \frac{1}{2}$ and $OP_2 = 2$. Then $OP_1 \times OP_2 = OP$. Let $OP = k$; then it is evident that there is an infinite number of points P_1, P_2 on the line such that $OP_1 \times OP_2 = k$. A geometric transformation which replaces each point P_1 by a point P_2 such that $OP_1 \times OP_2 = k$ is called an inversion. In such case O is the centre of inversion and k is the radius of inversion. As P_1 moves nearer to O, P_2 moves farther away. As P_1 approaches P, P_2 approaches P. In general, when $xy = k$, x and y are inversely proportional, one decreasing as the other increases. Also, if $y = f(x)$, x may be considered inversely as a function (implicit) of y.

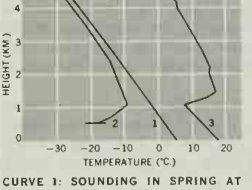
INVERSION OF TEMPERATURE. Over much of the earth the air temperature usually decreases with increasing elevation up to a height of 8 to 18 km. (5 to 11 mi.) above the surface. Frequently, however, layers of air are present through which the temperature increases with height instead of decreasing. Such layers are called inversions of temperature or, briefly, inversions. The rate of decrease of temperature with height is called the lapse rate. When the temperature increases with height, as in an inversion, the lapse rate is negative. Occasionally in meteorological articles the term inversion is applied loosely to any layer in which the lapse rate, though positive, is smaller than the lapse rates below and above it. In the following it will be used only in its strict sense.

Inversions are measured by (1) the thickness of the layer, (2) the rate at which the temperature increases and (3) the total rise in temperature through the layer. The last is called the magnitude of the inversion. Inversions with rapid rates of temperature increase are termed sharp, those which have large total temperature increase are called large and those which are sharp and large are called strong.

The lowest layer of the atmosphere, where the lapse rate is usually positive, is called the troposphere. As has been stated, however, even in the troposphere inversions are frequent, and in some regions they are invariably present at small or moderate heights. An examination of aerological soundings made in Sweden, for example, showed that inversions occurred in 44% of them and in 69% of those made in winter.

In the stratosphere, above the troposphere, the temperature normally is constant or increases slowly with height, and at higher levels it increases at a greater rate. The stratosphere is sometimes called the upper inversion, because the inverted state in this region is normal.

An inversion starting at the earth's surface is called a ground inversion, while one with normal temperature decrease in the layer of air below it is sometimes called a high inversion. In the accompanying figure, curve 1 shows the variation of temperature with height in a case of normal lapse rate at all levels; curve 2 shows a ground inversion, surmounted by a layer with normal lapse rate; and curve 3 shows a high inversion with normal lapse below and above.



CURVE 1: SOUNDING IN SPRING AT HAMBURG, GER., SHOWING NORMAL DECREASE OF TEMPERATURE WITH HEIGHT. CURVE 2: SOUNDING IN LATE FALL AT BISMARCK, N.D., U.S., SHOWING GROUND INVERSION. CURVE 3: SOUNDING IN SUMMER OVER PACIFIC OCEAN AT 30° N., 125° W., SHOWING TRADE-WIND INVERSION

Relation of Inversions to Weather.—Inversions play an important role in determining cloud forms, precipitation and visibility. The ease with which vertical motions of air parcels, and in particular vertical mixing, take place depends on the lapse rate. This can be understood readily when it is remembered that an ascending air parcel cools by expansion at the adiabatic rate of 1° C. per 102 m. rise if it is unsaturated, or a somewhat smaller rate if saturated. (*See* ADIABATIC PROCESSES IN ATMOS-

PHERE.) An inversion acts as a lid on vertical motions in layers below. The consequence is that convection produced by heating the air from below is limited to levels below the inversion, and diffusion of dust and smoke is likewise limited. In regions where a pronounced inversion is present at a low level, convective clouds cannot grow high enough to result in showers, and at the same time the visibility may be greatly reduced below the inversion, even in the absence of cloud, by the accumulation of dust and smoke particles. Because the air near the base of the inversion is cool, cloud or fog is frequently present there (*see* FOG).

The suppression of vertical turbulence allows inversions to act as slip surfaces across which the upper layers slide freely, unimpeded by the exchange of momentum with the lower layers. The resulting wind shear, together with the abrupt density change, may produce bumpiness in an airplane flight through the inversion, even though the actual atmospheric motion is smooth. This is caused by the sudden change in dynamic lift on a plane passing from air moving slowly to less dense air moving rapidly or from a different direction. Furthermore, if the inversion slopes (frontal inversion), the air above it may be carried upward along the slope because of its motion relative to the air below, and layer clouds and precipitation may result from the adiabatic cooling of the ascending air.

Except in the last-named case, of air being carried upward above a sloping inversion, the base of the inversion forms a quite sharp boundary between air with low visibility below and extremely clear air above. Because the inversion likewise limits water vapour diffusion it also usually represents a boundary between humid air below and very low humidity above.

Another important influence of inversions on the weather is the effect upon the diurnal range in temperature. The principal heating of the air during the day is produced by contact with the ground, the temperature of which is raised by solar radiation to which the air is transparent. The sun's radiation is absorbed by the ground, and the heat is communicated to the air by conduction and convection. Since the inversion base represents the upper limit to which heat is carried by convection, only a shallow layer of air will be heated if the inversion is low and large, and the temperature rise will be great. On the other hand, if the inversion is high or no inversion is present a deeper layer of air must be heated, and the temperature will rise less.

Ground Inversions.—These inversions are produced by cooling of the air by contact with a colder surface. The most general cause is cooling of the ground by radiation on clear nights, and for this reason they are also called nocturnal or radiation inversions. The radiation downward from the atmosphere is much less than that upward from the ground, resulting in a net loss of heat by the latter when the sun is not shining. The air in contact with the ground is cooled by conduction, and if the air is in motion, the cooling effect is transmitted upward by mixing of the air at the ground with that a little higher, as well as by radiation.

The effect of this turbulent mixing and radiational exchange is to increase the thickness and decrease the magnitude of the inversion. If the air is cooled below its dew point by this process, fog may result. When the wind is sufficiently strong, the turbulent mixing may wipe out the inversion at the ground, establishing an adiabatic lapse rate there and sharpening the upper part of the inversion. In this case if condensation occurs the fog is also raised from the surface to form "high fog" or stratus cloud in the coldest air just below the inversion.

Topography greatly affects the magnitude of ground inversions. If the land is rolling or hilly, the cold air formed on the higher land surfaces tends to drain into the hollows, producing a larger and thicker inversion above low ground, and little or none above the higher points.

Ground inversions are usually removed during the day by heating from below. The ground is warmed by solar radiation, and the air above it by conduction and convection. In middle latitudes in winter, however, the insolation during the day is often insufficient to offset the cooling which has occurred the previous night, and ground inversions are augmented day after day during periods of light winds. In these cases fog may persist both day and night. The great valleys of California and the valleys of central Europe are characterized by persistent fog of this type in winter.

Farther poleward, where little or no sunlight is received in winter, stagnating air is subjected to long periods of cooling at the ground. An inversion of great magnitude, considerable thickness and tremendous areal extent develops, blanketing the entire interior of high latitude continental areas, and also (in the northern hemisphere) the Arctic ocean. This inversion is known as the arctic (or, over the antarctic continent, the antarctic) inversion. It is strongest and most persistent in the central portion of continents at high latitudes.

Inversions beginning at the earth's surface are also formed when warm air flows over a colder surface. In this case also the air undergoes contact cooling which is carried upward by mixing, and if the mixing is intense the inversion may be dissolved at the ground and sharpened higher up. Among the places where inversions produced in this fashion are dominant, the Grand Banks of Newfoundland are outstanding. In one case, for example, the air temperature increased from 4° C. immediately above the sea surface to 21.5° C. at an elevation of 1,150 m. The persistent sea fogs of this region are caused by the cooling of the warmer air flowing over the cold sea surface. Similar inversions are produced over continents by the flow of warm air from subtropical regions over snow-covered areas in middle latitudes, particularly in spring when the latent heat of melting or evaporation of the snow is withdrawn from the air, increasing the cooling effect.

Turbulence Inversions.—Turbulent mixing in strong winds would establish an inversion even in the absence of a pre-existing one. The effect of vertical mixing in case of a normal lapse rate is to carry heat downward, cooling the upper part of the mixed layer, and heating the lower, until an adiabatic lapse rate is established. If the mixed layer had an abrupt top, the cooling would be a maximum there, and there would be an abrupt increase in temperature at that level. Instead, the mixing tapers off gradually, and above the thoroughly mixed adiabatic layer there is a finite layer of transition to the unmixed and therefore uncooled air above; *i.e.*, a turbulence inversion is established above the thoroughly mixed layer.

If an inversion is already present, stronger winds than otherwise are required to mix the surface air and establish an adiabatic layer, but if they occur, the inversion is raised to a higher level and sharpened. The cooling in the upper part of the mixed layer may produce stratus or stratocumulus cloud there, while the heating in the lower part may dissolve fog at the ground.

The formation of stratus or stratocumulus clouds by turbulence is very general. The stratiform sky is typical of anticyclonic weather over the British Isles and western Europe in winter. The cloudiness may persist for several days, but no rain, or at most a slight drizzle, falls from it. While turbulence is the principal cause of the cloud in this type of anticyclonic weather, another factor contributes considerably to the formation or strengthening of the inversion. This factor is called subsidence.

Subsidence Inversions.—By subsidence is meant the sinking and vertical shrinking of a layer of air. When a layer of air descends bodily, the increase in pressure compresses it, so that the upper portion descends farther than the lower. The heat of compression will be greater for the upper part than the lower, consequently, and the lapse rate of temperature will thus be reduced. If at the same time as it sinks the air layer spreads out horizontally, the upper portion will descend still more, and the compression may be sufficient to heat it to a higher temperature than the lower part, producing an inversion.

Near the ground the air, because of the influence of friction, tends to flow outward from anticyclones (areas of high atmospheric pressure), and the air above must sink to take its place. In addition, because of the dynamics of atmospheric motion, the air moving around anticyclones and in equatorward currents must spread horizontally and shrink vertically (*see* WIND). Subsidence thus occurs in anticyclones at all levels, and especially in their eastern portions, where the air flows toward the equator.

The areas which are dominated by anticyclones are: (1) the

northern portions of continents in winter; and (2) the subtropical oceans throughout the year. These regions, then, are the ones where subsidence inversions prevail.

The inversions associated with continental anticyclones frequently are dome-shaped. The base of the inversion layer may be from three to five kilometres high somewhat to the east of the centre of highest pressure and slope gently downward in all directions to a level of one kilometre or lower. Where the subsidence inversion is low, it may merge with the ground inversion to produce an extremely large and thick inversion. Whether or not they merge with ground inversions, low subsidence inversions in winter are usually associated with persistent fog or stratus cloudiness, with the valleys covered with cloud and the mountains which penetrate into the inversion enjoying clear mild weather.

Associated with anticyclones over the subtropical oceans there occur strong inversions with bases from 300 to 2,000 m. above sea level. Curve 3 in the figure shows a typical sounding taken through such an inversion. These inversions persist throughout the year in tropical regions, and follow the seasonal migration of the subtropical high-pressure belt, extending into middle latitudes in summer.

When the inversions over subtropical oceans were first observed they were called trade-wind inversions and were attributed to the difference in source of air between the trade winds, originating on the poleward side of the subtropical anticyclones at low levels, and the antitrades flowing over them from equatorial regions at greater heights. This name was retained, although it was established as additional data became available that the change in wind direction does not coincide in position with the inversion layer.

Another theory suggested for the formation of the trade-wind inversion was that it is produced by vertical turbulence. This theory, however, was belied by observations which showed that the inversion is too large to be formed that way, with temperatures aloft frequently higher than at sea level, and that it is highest in the region of equatorial calms and lowest in the regions of strongest trade winds. Turbulence would produce the highest inversion where the winds are strongest. Study of the increased number of observations available enabled the demonstration, in 1945, that the explanation of the trade-wind inversion lay in the subsidence associated with the subtropical anticyclones. Analysis of the winds in these regions showed that there is sufficient divergence in them to produce the extremely large sinking motion needed to create the pronounced inversion. Over most of the tropical regions the lapse rate below the inversion is kept nearly adiabatic by heating from below by warmer water, by radiation from cloud tops and by turbulence. Along the west coasts of North America and Africa, however, the air passes over a belt of cold water which rises from considerable depths. In these regions the air is cooled by the surface and the inversion sometimes starts at sea level. On the California coast an inversion at the surface may be produced also at times by winds from the continent subsiding down the high coastal mountain ranges.

The Weather Associated With Trade-Wind Inversions.—The air structure resulting from the processes described above consists of a cool humid layer next to the sea surface and a much warmer dry layer above it. Stratus or stratocumulus clouds are usually present from a few hundred feet above the sea to the base of the inversion. If the inversion starts at sea level, fog will occur if the air is cool enough, or the air may be cloudless. The slope of the inversion upward to the west and equatorward permits more active convection to take place and the clouds to grow higher in those directions. Where convective activity takes place the clouds tend to be broken, but their greater thickness makes showers possible.

While the stratus associated with the trade-wind inversion is characteristic of the eastern portions of subtropical and equatorial oceans, it is commonly referred to as west coast stratus because it is at the shore that it affects aviation and other human activities.

Since a large proportion of the earth's surface is covered by the trade-wind circulation, the trade-wind inversion is one of the major features in the structure of the atmosphere. The principal weather changes in low latitudes have been attributed to long waves in the inversion, convective showers occurring when the wave motion raises the inversion sufficiently high. The relationship of these waves to the genesis of tropical cyclones was studied, but no conclusive results were obtained. It appears to be definite that the formation of hurricanes or typhoons is associated with convergence which would lift the inversion and, offsetting the effect of earlier divergence and subsidence, wipe it out.

Frontal Inversions.—When a cold mass of air and a warm mass of air are side by side the cold one extends like a wedge below the warm one. The sloping boundary between the two air masses is called a front (*q.v.*). Because of mixing at the boundary, the front is not an abrupt discontinuity, but a transition zone. The warm air overlies the cold, and the transition zone represents a region where, in passing upward, the temperature increases from that characteristic of the cold air to the temperature of the warm air. Thus the frontal zone is an inversion.

The frontal inversion differs from the other inversions discussed in two respects: (1) it has considerable slope, while the others are nearly horizontal; (2) the humidity may be high and clouds may be present immediately above it. Frequently fronts, instead of being real inversions, have smaller positive lapse rates than the air masses below and above. In these cases the air above the front would be warmer than that below if brought to the same pressure. Because it is at a lower pressure, it actually has a lower temperature than the (potentially) colder air mass below. Because the warm air frequently is ascending over the cold-air wedge, and being cooled by expansion, actual inversions at fronts are rarely found at heights greater than two kilometres; at greater heights a slower rate of decrease of temperature almost always characterizes the transition zone, rather than an increase. On the other hand, there is frequently an inversion at the top of the cloud produced by the ascent of the warm air. Fronts and frontal inversions play a principal role in the modern theory of extratropical cyclones or depressions (*see* CYCLONE). Most of the precipitation in middle and polar latitudes in winter is associated with fronts.

Discussions of inversions in meteorological literature are spread through the treatments of the various associated phenomena: fog, clouds, haze, radiation, turbulence, and maximum and minimum temperature forecasting. The reader wishing further information on this topic cannot be directed to any single article or small number of articles. By looking at the index of any standard meteorological textbook he will be provided with additional material and with references to journal articles which enlarge upon the treatment given here. (Ms. N.)

INVERTEBRATE, any animal not possessing a backbone or vertebral column (*e.g.*, worms, snails, insects, sea stars). Invertebrates are distinguished from vertebrates (*q.v.*), all of which possess some kind of cartilaginous or bony axial skeleton. In modern systematic zoology, some invertebrate forms (amphioxus, tunicates, etc.) are included with the vertebrates in the phylum Chordata (*see* CHORDATE); thus the invertebrates do not constitute a homogeneous or natural taxonomic grouping, but the distinction between vertebrates and invertebrates remains a convenient one. It is estimated that more than 90% of all known species of animals are invertebrates. *See* INVERTEBRATE EMBRYOLOGY; ZOOLOGICAL NOMENCLATURE; ZOOLOGY; and references under "Invertebrate" in the Index. (J. M. A.)

INVERTEBRATE EMBRYOLOGY is the study of the development of a backboneless or invertebrate animal from the activated egg. Embryonic development is a phenomenon encountered only in multicellular animals (*see* EMBRYOLOGY). Protozoa (*q.v.*), the one-celled or acellular animals, are therefore disregarded; the Mesozoa (*q.v.*), a group of multicellular parasites of simple structure, are considered elsewhere.

Many lower invertebrates can reproduce more of their kind by asexual methods, but more commonly reproduction involves sexual methods. All animals composed of more than one cell reproduce sexually by means of eggs. In most cases the egg is activated to develop by union with a sperm cell; in other cases the egg may start to develop spontaneously without fertilization or may be

caused to develop by agents other than sperm cells (*i.e.*, parthenogenetically). Sex cells of various marine invertebrates have been used extensively for many studies concerned with details of the fertilization process, including the nature and roles of interacting substances produced by eggs and sperm and the nature and mode of action of parthenogenetic agents (*see* EMBRYOLOGY, CHEMICAL).

The study of comparative anatomy reveals that all vertebrates, or backboned animals, possess essentially the same basic body plan (*see* VERTEBRATE). The study of paleontology reveals the relatedness of all vertebrate classes because the fossil record is sufficiently complete to demonstrate the time course and nature of their evolution. Moreover, the study of comparative embryology demonstrates that the events of embryonic development are basically very similar in the eggs of all vertebrates except for those modifications that are primarily the consequence of differences in the amount of food stored in eggs as yolk (*see* VERTEBRATE EMBRYOLOGY), or that are the consequence of adaptations for development on land or inside the mother's uterus (*see* EMBRYOLOGY, HUMAN).

By contrast, the study of comparative anatomy of those animals lumped together as invertebrates reveals a number of basic body plans that differ considerably from one another and that often appear to be completely unrelated. Each group of animals characterized by one of these basic body plans constitutes a phylum. The phyla whose development will be discussed here are those recognized by Libbie H. Hyman. It is not possible in most instances to deduce any evolutionary relationships between any two phyla on the basis of comparative anatomy alone. The only invertebrate phyla shown to be closely related by comparison of adult structure are the Annelida (*q.v.*; earthworms, leeches, etc.) and Arthropoda (*q.v.*; insects, crustaceans, etc.). Moreover, the study of paleontology reveals little about the evolution of invertebrate phyla. By the Cambrian period, *i.e.*, by the end of the first two-thirds of the earth's history, all the major phyla were already present and readily distinguished from one another with the exception of the Chordata, comprising the vertebrates and allies. Unfortunately the bodies of many invertebrates are so delicate, and the rocks of the early periods have been so altered by heating, crushing and other processes, that it is impossible to obtain a fossil record sufficiently complete to demonstrate the time course and nature of the evolutionary changes that led to the origin of invertebrate phyla.

Since comparative anatomy and paleontology provide so little information about the descent of invertebrate phyla, a great deal of attention has been focused on detailed comparisons of embryonic development in different invertebrate phyla in the hope that these would provide some clues concerning the relationships among the phyla. The fundamental postulate on which this work was based was the belief that embryos of related organisms are more nearly alike than are the adults; *i.e.*, that evolutionary changes affect the early developmental stages less markedly than the later stages.

In general it is believed that the embryonic development of marine representatives of the various invertebrate phyla has been modified less during the course of evolution than the development of representatives adapted to life in fresh water, on land or as parasites. Consequently the study of descriptive and comparative embryology has deliberately stressed the marine forms. Since the middle of the 20th century, however, the emphasis in invertebrate embryology has been on the study of the mechanisms of cellular differentiation (*see* EMBRYOLOGY, EXPERIMENTAL). Eggs of many marine invertebrates have proved to be ideal material for many studies in experimental embryology because of their transparency, the ease with which fertilization can be controlled, the ease of culturing and observing them, their availability in large numbers, etc. For these reasons much more is known about the development of marine invertebrates than of invertebrates adapted to other habitats.

Embryonic Development.—For convenience, certain stages are distinguished in the development of all animal eggs, although they frequently merge into one another almost imperceptibly. During a given stage one kind of developmental change predominates. The major stages, in order of their appearance, are as follows:

Cleavage.—Division of the activated egg into smaller and smaller cells called blastomeres; the spatial arrangement assumed by the first few blastomeres constitutes the cleavage pattern.

Blastulation.—The special arrangement assumed by blastomeres at the end of the cleavage period and prior to the onset of gastrulation, often around some sort of fluid- or jelly-filled cavity called the blastocoel.

Gastrulation (Germ-Layer Formation).—Individual or mass movements of blastomeres to form localized groups or layers called germ layers. The outermost cells constitute the ectoderm and the innermost ones the endoderm. A primitive digestive cavity, the archenteron, usually forms within the latter. In animals above a certain level of structural organization, a third germ layer, the mesoderm, forms between ectoderm and endoderm. If a cavity arises within the mesoderm, it is called a coelom.

Organogenesis.—Establishment of organ rudiments through interaction and co-operation of germ layers.

Histogenesis.—Cellular differentiation within those germ layers involved in organ formation.

Development is said to be direct when the new individual at the time of hatching or birth requires only growth and further differentiation to attain the adult form. It is said to be indirect when the new individual at the time of hatching or birth differs markedly from the adult and is called a larva, which is a stage in the life history especially adapted for feeding and/or dispersal of the species. (*See* DEVELOPMENT, ANIMAL.) Adaptation of the larva to some way of life different from that of the adult necessarily means specialization of organs along lines that will not lead directly to the structure of adult organs. In this case attainment of the adult form requires complex and often sudden changes in structure (*see* METAMORPHOSIS) as well as growth and further differentiation. Sometimes several larval stages are encountered before the adult form is attained.

THE DEVELOPING EGG

Types of Eggs.—All eggs are alike in possessing a main axis of symmetry called the polar axis, the ends of which are named the animal and vegetal poles. This axis originates while the eggs are developing in the ovaries. The two poles often differ visibly in the amount of pigment, yolk or other inert materials concentrated near them. If the yolk is slight in amount and is more or less evenly distributed, the eggs are said to be isolecithal, alecithal or homolecithal. Large amounts of yolk tend to accumulate in one region of the egg, either in the vegetal half or the centre, leaving most of the protoplasm in the animal half or the periphery, respectively. Eggs with yolk concentrated vegetally are called telolecithal, those with central yolk centrolecithal. The latter term applies in the strict sense only after the nucleated masses of protoplasm arising within the egg during cleavage subsequently migrate to the periphery.

Cleavage Patterns.—The cleavage pattern depends in part upon the distribution of yolk in the egg, but also upon other cytoplasmic factors independent of the yolk. When cleavage involves the entire egg, it is said to be total or holoblastic. The most common patterns resulting from holoblastic cleavage are called radial and spiral cleavage. In either case the first two cleavage planes are meridional; *i.e.*, they pass through the animal and vegetal poles of the eggs and stand at right angles to each other. Thus, at the four-cell stage the egg is divided into four quarters (fig. 1[A]). The third cleavage plane is transverse; *i.e.*, at right angles to the

B, C AND D, EIGHT-CELL STAGES VIEWED FROM ANIMAL POLE

other two. In isolecithal eggs this transverse cleavage is usually equatorial, but in telolecithal eggs it tends to be latitudinal, shifted toward the animal pole, separating four smaller animal cells from four larger vegetal cells. In radial cleavage the four animal cells of the eight-cell stage lie directly above the four vegetal cells (fig. 1[B]), whereas in spiral cleavage the third cleavage planes form in such a way that the animal cells appear to have rotated relative to the vegetal ones, with the result that each of the blastomeres at the animal pole lies directly above the cleavage plane separating two of the cells at the vegetal pole (fig. 1[C]). Holoblastic cleavage results in three other cleavage patterns in invertebrates, although less frequently. One of these, known as biradial or disymmetrical cleavage, occurs only among the comb jellies (phylum Ctenophora) (fig. 1[D]). Another, called bilateral cleavage, is especially striking because of the bilaterally symmetrical arrangement of the blastomeres (fig. 1[E]). The third is called irregular cleavage because the exact cleavage pattern in any given egg is unpredictable.

When cleavage involves only part of the egg, it is said to be partial or meroblastic. If the yolk is markedly concentrated at the vegetal pole, cleavage may be restricted to a cytoplasmic cap at the animal pole (fig. 1[F]); such a cleavage pattern is called discoidal cleavage. In the case of centrolecithal eggs cleavage is said to be superficial, since the blastomeres are located on the surface of the yolk.

Regulative *v.* Mosaic Development (Indeterminate *v.* Determinate Eggs).—It is possible to separate the individual blastomeres of invertebrate eggs from one another to determine their individual developmental capacities. When Hans Driesch carried out this simple experiment in the two- and four-cell stages of sea urchin eggs, he made the momentous discovery that each half or each quarter of the original egg is capable of developing into a normal, but small, sea urchin larva (*see* EMBRYOLOGY, EXPERIMENTAL). This type of development, in which a part can regulate or modify its developmental course to form the whole, is called regulative, and the eggs capable of such development are called indeterminate. This term implies that the developmental fate of the blastomeres has not been determined or decided in early cleavage stages. In indeterminate eggs the ultimate developmental fates of the blastomeres apparently depend to a considerable extent on their positions relative to other blastomeres and upon cellular interactions among blastomeres.

When similar experiments are performed on the eggs of certain other invertebrates, for example on those of tunicates (ascidians), exactly the opposite result is obtained. Isolation of one blastomere of the two-cell stage results in formation of exactly half a larva, and isolation of one blastomere of the four-cell stage leads to formation of exactly one-fourth a larva. This type of development, in which a part of an egg, when isolated, can form only the part of the animal that normally would have been derived from it, is called mosaic development, and the eggs that undergo such development are called determinate. This term implies that the developmental fate of the blastomeres has been determined in early cleavage stages.

In mosaic development the fate of a particular blastomere appears to depend upon the specific portion of the cytoplasm segregated into it at the time of cleavage. This would imply that different localized areas of the cytoplasm of uncleaved eggs possess different morphogenetic capacities; *i.e.*, the existence of a cytoplasmic localization of organ-forming areas in the uncleaved egg. This, indeed, appears to be the mechanism of cellular differentiation in mosaic eggs. For example, in the eggs of certain annelids and mollusks a special portion of the cytoplasm becomes localized and constricted off partially into the so-called first polar lobe. Subsequently this portion of the cytoplasm becomes incorporated into one of the first two blastomeres. If this polar lobe is cut off before the first cleavage occurs, so that its contents cannot be added to one of the first two blastomeres, a defective larva results. It is incapable of forming the special apical tuft of cilia as well as the entire body region posterior to the prototroch (swimming organ). Thus the portion of the cytoplasm that enters the first polar lobe contains factors of some sort that are essential to formation of

the apical tuft and posttrochal region. It is known that definite substances (enzymes, vitamins) tend to be localized in definite regions of mosaic eggs, but whether these particular substances play a role in determination of morphogenetic potencies of localized areas is unknown. (*See* EMBRYOLOGY, CHEMICAL; EMBRYOLOGY, EXPERIMENTAL.)

Eggs that undergo spiral cleavage are characterized by mosaic development, but this type of development also occurs in a few eggs that do not undergo spiral cleavage. Actually, the distinction between indeterminate and determinate eggs is not as rigid as is suggested by these examples. Isolated animal and vegetal halves of sea urchin eggs cannot develop into normal larvae, so not all regions of so-called indeterminate eggs are capable of regulation into completely normal individuals. Moreover, fragments of uncleaved determinate eggs of certain species are capable of regulation into normal larvae. But for practical purposes the distinction between indeterminate and determinate eggs is a useful one.

Cell-Lineage Studies.—In the case of determinate eggs it is possible to follow the developmental fates of individual blastomeres and their progeny with great accuracy by direct observation and thus to determine the exact parts of the body of the larva that form from each blastomere and its derivatives. Such studies are called cell-lineage studies. They have been pursued with remarkable success by many famous American embryologists.

For example, the spiral cleavage pattern of the eggs of many annelids and mollusks is remarkably similar (fig. 2[A]). It is characterized by the formation from the first four blastomeres (conventionally designated as A, B, C and D) of four quartets of smaller cells (micromeres, labeled and numbered according to their origin and time of appearance as, for example, 1d, 2d, 3d and 4d, the four micromeres derived from blastomere D) toward the animal pole and one quartet of larger cells (macromeres) toward the

vegetal pole. The first three quartets and their offspring form the ectoderm, with the exception of cell 2d, which also produces ectomesoderm in some species (*see* below). Micromere 4d gives rise to the two teloblast cells, each of which produces a mesodermal band, the entire source of the endomesoderm (*see* below), in addition to producing endoderm. The remaining cells of the fourth quartet and all four underlying macromeres at the vegetal pole produce only endoderm. Actually, the cell lineage is known in much greater detail than this. For example, it is known that four large ciliated cells of the prototroch arise in each quadrant by two successive divisions of one of the daughter cells arising from the first quartet micromere, whereas the other daughter cell produces other specific cell types in appropriate numbers (fig. 2[B]).

Blastulation.—Several types of blastulae are encountered commonly in invertebrate development: (1) coeloblastula, a hollow blastula in which the blastomeres arrange themselves around a cavity, the blastocoel, which may be large or small, centrally placed or displaced towards the animal pole; (2) stereoblastula, a type of solid blastula in which all cells extend from the surface to the centre of the egg; (3) morula, another type of solid blastula containing cells in the centre that do not reach the surface, and vice versa; (4) superficial blastula (periblastula), in which the blastomeres are located at the surface of a central yolk mass; and (5) discoblastula, a disc of blastomeres resting on the uncleaved portion of the egg.

FORMATION OF GERM LAYERS

Endoderm Formation.—Endoderm formation occurs in several ways in eggs of invertebrates. By embolic gastrulation or invagination one portion of the wall of a coeloblastula folds within the rest, thus forming a blind sac lined with endoderm; the external opening from this sac is the blastopore. By epibolic gastrulation or epiboly the small blastomeres of the animal hemisphere overgrow the large cells of the vegetal hemisphere; the uncovered area at the vegetal pole represents the blastopore, but it eventually disappears when overgrowth is complete. In involution the cells turn under and extend beneath the ectoderm to form endoderm, usually in meroblastic eggs; a modification of epiboly. In unipolar ingression the cells at the vegetal pole withdraw into the interior singly or en masse. Multipolar ingression occurs when the cells over the entire surface of the blastula withdraw singly into the interior. In delamination the inner ends of the cells of the coeloblastula are cut off by cleavage planes to become endoderm. A blastopore is lacking in those cases where endoderm formation is by ingression or delamination.

Blastopore: Mouth *v.* Anus.—In most of the invertebrate phyla the blastopore persists as the mouth opening of the digestive tube, or the mouth forms approximately where the blastopore closed. In other invertebrate phyla the blastopore persists as the anal opening, or the anus forms approximately where the blastopore closed.

Formation of Mesoderm and Coelom.—There are two kinds of mesoderm, which appear to be phylogenetically distinct: ectomesoderm and endomesoderm. Ectomesoderm is always mesenchymal and typically consists of ectodermal cells that wander into the interior. It is present in the Radiata and in the Protostomia (*see* below). Where cleavage is spiral, ectomesoderm arises from one or more cells of the second and/or third quartets. Endomesoderm arises from or with endoderm; it is referred to as true mesoderm. The coelom always arises as a cavity within endomesoderm.

Endomesoderm originates by several methods: (1) teloblastic method—the 4d cell of eggs exhibiting spiral cleavage divides to form two teloblast cells, which move into the blastocoel, each proliferating a mesodermal band; (2) derived mesodermal band method—endomesoderm comes from paired bands that arise from a mass of cells around the blastopore; once formed, these bands behave much the same way as those originating from teloblast cells; (3) enterocoelous method—the mesoderm is formed in whole or in part by the outpouching of the archenteron wall; (4) lamellar method—the mesoderm grows out as a flattened layer of cells around the blastopore; it is commonly regarded as a modified enterocoelous method; and (5) mesenchymal method—formation of endomesoderm by inwandering of endoderm cells en masse or more or less singly; it may be combined with other methods of mesoderm formation.

The coelom is spoken of as an enterocoel or as a schizocoel, depending on its method of formation. An enterocoel (fig. 2[C]) is the cavity of the pouch or pouches arising from the wall of the archenteron and is thus continuous initially with the archenteron. It and the enterocoelous mesoderm therefore originate simultaneously during embryonic development. A schizocoel originates as a cavity within the endomesoderm that arises as solid masses from teloblasts, derived mesodermal bands, lamellae or mesenchyme (fig. 2[D]). It is never continuous with the cavity of the archenteron and originates later in embryonic development than the mesoderm surrounding it.

PHYLOGENETIC SIGNIFICANCE OF EMBRYOS AND LARVAE

Embryonic Basis for the Diphyletic Theory of Origin of Phyla.—The so-called higher phyla, *i.e.*, those whose structural complexity exceeds that of the Protozoa, Mesozoa, Porifera, Coelenterata and Ctenophora, appear to fall quite naturally into two major groups on the basis of four features of embryonic development discussed thus far, namely: (1) the fate of the blastopore or blastopore region; (2) the cleavage pattern; (3) the time of determination of the fates of the blastomeres; and (4) the method of coelom formation.

Those phyla whose blastopore or blastopore region becomes the anus are grouped together as the Deuterostomia: Chaetognatha, Pogonophora, Echinodermata, Hemichordata and Chordata. Members of these phyla are usually characterized by radial cleavage, indeterminate eggs (regulative development) and the enterocoelous method of coelom formation. Those phyla whose blastopore or blastopore region becomes the mouth are grouped together as the Protostomia. Members of these phyla are characterized in general by spiral cleavage, determinate eggs (mosaic development), and usually by the schizocoelous method of coelom formation. The Protostomia include the following phyla that possess a coelom: Ectoprocta (Bryozoa), Phoronida, Brachiopoda, Mollusca, Sipunculida, Echiurida, Annelida and Arthropoda. Moreover, even though they fail to form a coelom, the acoelomate phyla—Platyhelminthes and Nemertina—as well as the pseudocoelomate phyla—Acanthocephala, Aschelminthes and Entoprocta—are lumped together with the Protostomia because their development is similar to that of the Protostomia in other aspects.

Thus the study of comparative embryology of the invertebrates suggests that there have been two major lines of evolution of the higher phyla. This concept is known as the diphyletic theory of origin of phyla. It is believed that the features of embryonic development used to set the Deuterostomia apart from the Protostomia are so fundamental that there is little likelihood that they would vary readily in adaptation to different habits and habitats. Hence they are reliable indicators of the relationships of invertebrate phyla.
